CIVIL ENGINEER AND ARCHITECT'S

NEW YORK
PUBLIC
LIBRARY
JOURNAL

SCIENTIFIC AND RAILWAY GAZETTE.

VOLUME V.—1842.

LONDON:

R. GROOMBRIDGE, 5, PATERNOSTER ROW;

H. HOOPER, PALL MALL EAST; J. WEALE, 59, HIGH HOLBORN; J. TAYLOR, 1, WELLINGTON STREET, STRAND;

WILEY & PUTNAM, NEW YORK; GALIGNANI, PARIS.

American Steam Pile Driving Machine.

INDEX.

- ACADEMY OF SCIENCES, Paris, Proceedings of, 66, 137, 170, 242, 265, 347.
- Academy, Royal, exhibition of, 232, 238, 262, 294.
- Ainslie's brick and tile machine, 427.
- Algemeine Bauzeitung, 178.
- American pile-driving machine, 1.
- American canals, 73, 105, 361.
- Antiquities, *vide* Architecture.
- Angoulême, 149; Athens, 411; baths, 221; canals, 97; Cologne, 224; Egyptian, 45, 127, 411; Elgin marbles, 249; Hereford, 374; lithochromy, 249; Mexican, 185; Mycenæ, 217; Palmyra, 412; Poitiers, 69, 113; Sardis, 218; theatres, 390; thermæ, 221; tombs, 217; Westminster, 32.
- Apparatus, *vide* Machine.
- Aqueducts, 24, 264.
- Pennsylvanian, 361.
- Arch, *vide* Bridge, vault in architecture, its origin, forms, and properties, 251.
- Semi, on the development of, 370.
- Skew, theory of, 156, 388; history of, 39, 102.
- Stone beam, Lincoln, 299.
- Architects, British, Royal Institute of, meetings, 27, 98, 126, 170, 204, 321, transactions, 258, 295, 297.
- bequest to, 253.
- chronological table of, 17.
- congress of, 369.
- Architects, Alexander, Mr., 30; Atkinson, Mr., 27; Barry, Charles, 87, 139, 217, 233, 397; Bartholomew, Alfred, 294; Burton, Decimus, 392; Cockerell, Chas. R. 232; Cuffley, Mr., 27; Culshaw, Mr., 278; Donaldson, T. L., 31, 233, 411; Duff, T. J., 175; East, F., 181; Elmes, W. H. L., 30, 233; Ferrey, B. 30, 233; Foulston, J. 68, 77; Godwin, Spencer, 69, 113, 149, 225; Goldicutt, S., 372; Green, J. B., 40; Hanson, Joseph, 209; Hardwick, P., 57; Holking, W., 30, 38, 67, 91, 411; Lamb, E. B. 234; Mallinson, James, 65; Michael Angelo, 216; Millar, Mr. 67; Moseley, Mr. 27; Pugin, A. W., 27, 118, 121, 211, 232; Savage, Mr., 392; Scott, Mr., 27; Smirke, Sir Robert, 232, 247; Smirke, Sidney, 392; Tattersall, R., 175, 211; Tottie, Carl, 234; Treinson, A., 234; Walker, T. L., 31; Wallace, Robert, 33; Walters, E., 27; Williams, A. and C., 278; Wren, life and works of, 224, 325; Wyatt, Mr., 233.
- Architectural criticism, 24, 37.
- Draughtsmen, British Association of, 389.
- Drawings, exhibition of, 232, 238, 262, 294, 389.
- Honours, 139.
- Precedent, 36, 82.
- Society, 98, 127; Yorkshire, 322, 399, 408, 422; societies, 408.
- Architecture, *vide* Building, Candidus, Competition, Decoration, Ecclesiastical.
- Architecture, Angoulême, 149.
- ancient and modern, *rev.* 29, 424.
- arch, 251, 370.
- astylar, 79.
- beauty, 76, 106.
- bar windows, 367.
- Byzantine, 150.
- Canova, 81.
- caryatides, 76.
- columns, 79, 127.
- Dublin, 78.
- ecclesiastical, 117, 141.
- Egyptian, 45, 79, 127, 411.
- entablatures, weight of, 298.
- friezes, 81.
- Gothic, 69, 79, 260.
- Gothic tracery, 204.
- Grecian, 146, 148, 217.
- introductory lecture on, by Dr. Fulton, 78, 127; ditto by Hosking, 91, 411; ditto by Donaldson, 411.
- iron, use of, 126, 235, 252.
- Italian, 106.
- lithochromy, 249.
- Manchester, 27.
- Michael Angelo, 217.
- Mexican, 45, 185.
- origin of, 148.
- Palladian, 79, 397.
- picture galleries, 10.
- Poitiers, 69, 113.
- polychromy, 290.
- professors, 31, 411.
- Russian, 297.
- sculpture in, 281.
- spires, 121.
- spirit of, 246, 295.
- staircases, 86.
- theatres, 390.
- Vitruvius, 38, 79, 248, 336, 411.
- Art and Protestantism, 141.
- Art Union, 170.
- Artesian well, Lille, 137; London, 184; Paris, 395.
- Asphalte roofing, 284.
- Axle, *vide* Railway, Locomotive.
- Auxiliary steam power, use of, in navigation, 118, 174.
- BANK NOTE PRINTING MACHINE, 385.
- Baths, Thermæ, of ancient Rome, with engravings, 221.
- Beale's rotary engine and boiler, with engravings, 181.
- Beam, *vide* Arch, Iron.
- Beatson's valve closet, with engravings, 174.
- Belgium, industrial state of, 61.
- Beton, 58, 276.
- Biography—Antolini Cavalier, 139; Birkbeck, Dr., 25; Chantrey, 24; Chapman, W., C. E., 39; Dannecker, 25; Foulston, J., 68; Goldicutt, J., 372; Haydon, B. R., 207; Huddart, Capt. 167; Seaward, Samuel, 209; Wilkie, 355; Wren, 325.
- Boiler, *vide* Marine engine, Steam engine.
- Bologna Academy, 393.
- Borrie's P., engine, with engraving, 213. 400.
- Boulton & Watt's direct action engine the Virago, 44, 400.
- Breakwater, *vide* Hydraulic, Engineering.
- Brick, *vide* Material; brick lighter than water, 393; making, improvements in, 8, 61.
- Bridge, *vide* Aqueduct, Arch, Viaduct.
- Brick and tile machine, Ainslie's, 427.
- bar iron, 53, 224.
- Bolton and Preston Railway, 388.
- building of, 58.
- cast iron, 226.
- comparison of bar iron and iron wire, 53, 224.
- Danube suspension, 359.
- Ereyburg, 224.
- iron, 53, 58, 224, 226, 249, 279, 291, 335.
- Kingston, 418.
- Lucca, 167.
- measurement of, 174.
- Newcastle, 359.
- Pont du Carrousel, 279.
- Scotswood suspension, with plate, 397.
- Skew, 40, 242.
- Sunderland, 335.
- Suspension, 53, 224, 391; Dredge's, 396.
- tension bar, 291.
- Tulow, 385.
- Wire, 53, 224.
- British Association, 273, 314.
- Building, notes on, *vide* Arch, Architectural, Beam, Brick, Cement, Chimney, Girder, Materials, Roof, Stone, Tile, Wood.
- Building, fireproof, 333.
- flooring, 333.
- foundations, 57.
- girders, cast iron, 228; trussed, 291; fireproof, 333.
- Prussia, 297.
- sandstone, 102.
- stonebeam, Lincoln, 299.
- stone vaulting, 258.
- Buildings, *vide* also Ecclesiastical.
- Alliance Fire-office, 336.
- Bath Savings Bank, 30.
- Brunswick Buildings, 278.
- College, Independent, Manchester, 27.
- Collegiate Institution, Liverpool, 30.
- Coblentz, 32.
- Conservative Club, 244.
- Dublin, 78.
- Exchange, Hamburg, 139.
- Fitzwilliam Museum, 87.
- Hall of Commerce, Threadneedle-street, 21, 31, 245, 295, 338.
- Liverpool, 278.
- Liverpool Collegiate Institution, 30; St. George's Hall, 30.
- Manchester, 27.
- Music Hall, 209.

- Palace of Moorshedabad, with engravings, 151, 205.
 Pantheon of Bavaria, 139.
 Paris, 139.
 Penitentiary, Pennsylvania, 29.
 Poitiers, 69.
 Prussia, 297.
 Reform Club, 87, 122.
 Royal Exchange, 62.
 Socinian Museum, 21.
 Strawberry Hill, with engravings, 182, 244.
 Town Hall, Birmingham, 209; St. Anstle, 244.
 Wren's buildings, 325.
 Windsor stables, 393.
- CANAL, *vide* Hydraulic Engineering.**
 American, 73, 105, 361; ancient, 97; Katwyk, 387; Colchester, 359; Dutch, 387; Glo'ster and Ledbury, 360; inclined planes, 105; Lehigh, 73; Morris, 105; Pennsylvania, 361; sluiceways, 73; Ulster, 125.
- Candidus's Note-book, 21, 37, 76, 106, 149, 178, 216, 247, 290, 336, 368, 397.
- Carpets, 10.
- Cast Iron, *vide* Iron Bridges, notes on, 226.
- Cathedral, *vide* Ecclesiastical Building.
- Cement, *vide* Materials, Fresco.
 beton, 58, 276.
 caoutchouc, 324, 395.
 concrete, 58, 276.
 Jeffrey's, 211, 395.
 Keene's, for fresco, 278.
 lithic, 28.
 Martin's 308, 337.
 puzzolana, 347.
 stucco paint, 323, 427.
- Cemetery, Edinburgh, 260.
- Chimneys, regulation of, 172; St. Rollox, 294.
- Chantrell, R.D., on lightning conductors, 320.
- Church, *vide* Ecclesiastical Building.
- Chubb's well safe, with engravings, 31.
- Chalk Basin, London, periodical drainage of, 383; supply of water from, 238; formation, outbursting of water from, 238.
- Clarke, Hyde, F.L.S., on colour, as applied to decoration, 9.
- Cologne Cathedral, on the restoration of, by George Godwin, Jun., 225.
- Colour, *vide* Decoration.
- Combustion, *vide* Fuel.
- Compass, variation of, 181, 283, 323, 353, 392, and 428.
- Competition, 21, 57; pump-room, Harrowgate, 65; Kidderminster, 179, 237; Candidus on, 247.
- Conductors, lightning, with engravings, 103, 229, 277, 321, 357.
- Copper sheathing, history of, 169.
- Cormorant steam frigate, 428.
- Cornish, and Boulton and Watt engines. by T. Wicksteed, *rev.* 426.
- Cymagraph for copying mouldings, with an engraving, 219.
- DAQUERRETYPE, 284, 348, 358.
- Decoration, *vide* Fresco.
 buildings, list of, 64, 305; carpets, 10; furniture, 10; leather hangings, 358; lithochromy, 249; picture frames, 10; polychromy, 290; use of gold in, 7, 9; use of colour in, 9.
- Denton, J. B., on model mapping, 56.
- Design, schools of, in the 17th century, 53.
- Diving Bell experiments, Payerne's, 331, 388, 408; machine for working, 351.
- Docks, London, 167; Woolwich, 323; Southampton, 359.
- Door knobs, 358.
- Drainage, Smith of Deanston on, 340.
- Drawing, *vide* Fine Arts, Surveying.
- Dredging bars, 50; *vide* Hydraulic Engineering.
- Dyer, Charles, on fireproof building, 334.
- EARTHWORK, Essay on, 84, 186; notes on, 336, 403; *vide* Engineering.
- East, Frederick, hints on architectural criticism, 24, 37, 86, 136.
- Ecclesiastical architecture, remarks on, 107, 141.
- Ecclesiastical Buildings—All Saints, Gordon-square, 234; Angoulême cathedral, with engravings, 149; Belgium, 393; Bruges, 393; Burgos cathedral, 37; Calcutta cathedral, 211; Cologne cathedral, 224, 393; commissioners, 380, 389; Dundalk Roman Catholic church, 175; fires in, 55; Hereford cathedral, Professor Willis's report on, with engravings, 374; Kentish Town church, 294, 324; Kidderminster new church, 179, 237; lightning conductors, 103, 229, 277, 321, 357; Lincoln cathedral, 299; Manchester churches, 27, 211; Norwich cloisters, vaults of, 98; Notre Dame, Poitiers, with engravings, 113; Poitiers, 69, 113; Portaferry church, 67; Russian, 297; St. George's Chapel Royal, 393; St. Hilary, Poitiers, 113; St. Martin's in the Fields, 393; St. Mary's Southwark, 30; St. Mary's Wareham, 393; St. Nicholas, Civray, with engravings, 150; St. Nicholas, Hereford, 323; St. Paul's, 323, 395; St. Peters, Poitiers, 71; St. Peters, Rome, 329; St. Porchaire, Poitiers, 114; St. Radegonde, Poitiers, 115; Scotch church, Crown-court, with engravings, 33; spires, 121; Sunderland church, 31; Temple church, 392, 403; Trinity chapel, Poplar, 30; Unitarian chapel, Stockport, 175; West Hackney church, 243; Wilton church, 233; Wren's buildings, 325; York Roman Catholic cathedral, 211.
- Ecclesiastical commissioners, 380, 389, 408.
- Ede's chemical laboratories, 68.
- Electric circuit, experiment on, 395.
- Electricity of whirlwinds, 395.
 lightning conductors, 103, 229, 277, 321, 357.
- Electrotint, 67.
- Electro-magnetism as a motive power, 234, 394.
- Encaustic, *vide* Fresco.
- Engineering, *vide* also Arch, Beam, Building, Diving-bell, Gas, Hydraulic, Locomotive, Machine, Material, Marine Engine, Mining, Motive Power, Paving, Railway, Steam, Steam-engine, Tile, Tunnel, Water, Wood.
- Engineering, ancient, 59; aqueducts, 24, 264, 361; chalk formation, 104, 238; clay, London, 59; cutting, 60; earthwork, 59, 84, 186, 402; notes on, 336, 403; foundations, Indian, 58, 168; history of, 96; lectures on, by Professor Vignoles, C.E., 57, 95, 127, 136, 165, 196, 230, 263, 345, 380; pile driving machine, American, 1; pressure of earth against walls, 317; retaining walls, 95; sheet piling, 57; sinking, 386; slips, 60, 95, 127; spring of water, outbursting of, 104; study of, 56; tippler, 336; tubbing, 386; tunnels, 264; viaducts, 264; Yankee geologist, 395.
- Engineers, blind, 97; convention of, 62; Acraman, Mr., 103; Adie, A. J., 388; Baker, W. L., 126; Bateman, J. F., 26; Beale, Mr., 181; Birch, E., 26, 397; Blackmore, Mr., 40; Boulton, Mr., 40; Bruff, Peter, 56; Brunel, I. K., 40; Brunton, W., 212; Buck, G. W., 40; Casebourne, T., 125; Chapman, W., 39; Clarke, Hyde, 7, 9; Dixon, J., 40; Dockray, R.B., 115; Dodd, G., 59; Donkin, Bryan, 385; Ewart, Peter, 360; Fairbairn, W., 138, 284, 314, 428; Gibbs, Mr., 102; Gurney, Goldsworthy, 28, 324; Gutzmer, Mr., 5; Green, John, 397; Grantham, John, 8, 124, 254; Hadden, J. C., 104; Hall, Samuel, 212; Huddart, Captain, 26, 167; Jackson, G. B. W., 126; Lawrie, J. G., 155; Losh, W., 65, 175; Maudslay, Mr., 31, 103, 104, 107; Miller, Joseph, 138, 177; Napier, David, 6, 324; Napier, Robert, 175; Nasmyth, James, 285; Nicholson, Robert, 40; Oldham, John, 385; Palmer, H. R., 176; Parkes, Josiah, 134; Penn, Mr., 5; Phipps, Mr., 65; Pole, W., 134; Rennie, G., 28, 109; Seaward, Samuel, 6, 118, 209; Sosastros, 59; Stephenson, George, 40, 59; Stephenson, Robert, 38, 238; Stevenson, David, 119; Telford, 59; Timperley, J., 203; Trewitt, Mr., 35, 104; Vignoles, professor, 57, 95, 363; Welch, H., 46; Woodhouse, S. J., 40.
- FINE ARTS, *vide* Architecture, Decoration, Fresco, Schools of Design.
- Fine arts, report of the Commissioners on, 302, 353.
- Fireproof building, Dyer on, 333.
- Flywheel, a few observations on, and on its application to the steam-engine, 364.
- Force of wind and sea, 189.
- Fresco, ancient, 78.
 account of, 171, 353.
 Bavarian, 308.
 Cornelius on, 306.
 detaching from the wall, 355.
 English, 305.
 government report on, 302, 353.
 Hampton Court, 128.
 Haydon on, 207, 261.
 Keene's cement for fresco, 278.
 Latilla on, 171.
 in London, 305.
 Parris on, 98.
 Severn on, 161, 188, 310.
 Simpson's, 278.
 on slate, 84.
- Fuel, consumption of, C. W. Williams, 40, 101, 129, 192, 252, 279.
- Furnaces, gas smelting, 62; development of gases, 137.
- Furniture, 10.
- GALVANOPLASTIC PROCESS, 395.
- Gas, dilation of, 137.
- Gas furnaces for iron, 62.
 meters, Defries's, 205; unfairness of, 392.
 purification of, 137.
- Gillot's patent stove for heating and ventilating, 427.
- Girders, cast iron, table of, strength of, 228, 291; trussed, table of, strength of, 291; wood, table of, strength of, 293.
- Godwin, George, Jun., F.L.S., Pen and Pencil Sketches in Poitiers and Angoulême, 69, 113, 149; on the restoration of Cologne cathedral, 224.
- Gold, use of, in decoration, 7.
- Grantham, John, C.E., paddle wheel disconnecting apparatus, with engravings, 8; on iron, as a material for shipbuilding, 124, 254.
- Green, John, Scotswood suspension bridge, 397.
- Guide screw stock, 373.
- Harbour, *vide* Hydraulic Engineering.
 Aberystwith, 428; Boulogne, 359; Port Talbot, 419.
- Haydon, B. R., on fresco, 206, 261.
 on schools of design, 413.
 on the Wilkie exhibition, 355.
- Holborn-hill, improvement of, 199.
- Hood, Charles, on lightning conductors, 357.
- Hosking, Professor, lecture on architecture, 91.
- Hydraulic Engineering, *vide* Aqueduct, Bridge, Canal, Dock, Draining, Embankment, Harbour, Lighthouse, Machine, Mill, Pier, Water.
- Hydraulic propulsion on railway, 406.
- Hydraulic engineering:—
 Bann reservoirs, 26.
 breakwater, floating, Reid's, 153, Algiers, 277; Jones on, 318; ancient, 319; Madras, 319.
 coffer dam, 58.
 diving bell, 331, 351, 388, 408.
 dredging bars, 50; dredging machine, steam, 351.
 embankment, 190; Hughes', 186; Heller, 319; Calder, 320.
 force of wind and sea, 189.
 foundations, 58, 168.
 self acting weir, 277.
 Shannon improvements, 417.
 sheet piling, 57.
 sluice gates, Katwyk, 387; Rotterdam, 277; Lehigh, 73.
 sluice, Chelsea meadow, 168; Bateman's, 277.
 Thames embankment, 177.
 Weir, Killaloe, 417; self-acting, 277.
 Whitby Pier, 359.
- INDICATOR, steam engine, Moseley's, with engravings, 268, 288; Penn's, 321; Russell's, 277.
- Ink, indelible, 137.
- Institute of Civil Engineers, proceedings of, 26, 125, 167, 199, 238, 242, 265, 318, 348, 383, 418.
- Institute of British Architects, *vide* Architects.

- Iron, *vide* Materials.
anthracite, 260.
action of air and water on, 275, 368.
cast, bridges, notes on, 226.
effect of water on, 352.
corrosion of, in boilers, 199.
changes in internal structure of, 418.
hot and cold blast, strength of, 314, 415.
as a material for ship building, 124, 254, 386.
relative properties of, 415.
sheathing, 386.
strength of, 178, 227.
use of, in architecture, 126, 235, 252.
works, use of gas furnaces in, 62; description of, 168, 416.
wrought, tenacity of, 285.
- Irving, William, tile machine, with engravings, 8, 61.
- JARMYN, G. A., drawings, 4.
- KALSBOMINE, 278.
- Kyanizing tanks, 202.
- LAURIE, J. G., on the economy of fuel in marine engines by expansion, 155.
- Leather hangings, Leake's, 358.
- Lecture, *vide* Architecture, Fresco, Vignoles.
- Lightning conductors, with engravings, 103, 229, 277, 321, 357.
- Lighthouse, ancient, 59; light of all nations, with engravings, 357, 401; Eddystone, 59; Maplin, with engravings, 60, 352; Menai, 318.
- Lithochromy, report on, 249.
- Liverpool Pavilion, with engravings, 4; architecture, 278.
- Lock, Gerish's, 204.
- Locomotive engine, *vide* Railway.
- Locomotive engine, electro-magnetic, four wheel, experiment on, 242; marine engine, 283; power, cost of, 381; Stephenson's, 37; straight axles, 273; theory of, 165.
- MACHINE, *vide* Steam Engine, Marine Engine, wheel.
- Machine, astronomical clock, Straaburg, 396; bank-note printing, 385; Barker's mill, 267; breast-wheel, 265; dredging, steam, 351; forging, new 358; guide screwstock, with engravings, 373; horizontal water wheel, 265; overshot wheel, 265, 266; pile driving, American, with engravings, 1, 135; rope, flat, for sewing, 26; stone boring, Hunter's, with engravings, 351; straps for driving, proportion of, with engravings, 35; sugar making, with engravings, 410; tile, Irving's, with engravings, 8, 61; tippler, for earthwork, with engraving, 336; turbine, 265, 267; undershot wheel, 265; water pressure, 126, 267; water power, 265; watch making, 395; windmill, new, 170; Yankee geologist, 395.
- Marbles, inlaid, 160.
- MARINE ENGINES, *vide* Fuel, Motive Power, Steam Engine, Steamboat.

THE

CIVIL ENGINEER AND ARCHITECT'S

JOURNAL,

THE AMERICAN STEAM PILE DRIVING MACHINE.

(With an Engraving, Plate I.)

IN our last number we gave a brief account of this machine, which has been exhibited for the last two months at Smith's Wharf, Pedlar's Acre, Lambeth. Our information was principally obtained from the engineer, but since then we have had an opportunity of more carefully examining the machine, and obtaining some accurate particulars, together with a correct drawing of the machine, taken expressly for the Journal. The machine was imported into this country from the United States, by Colonel Cowdin, and some other parties, and consists simply of a locomotive engine, similar in principle to those used on our railways, having two inclined cylinders with their connecting rods, working upon cranks attached to the axes of two crab engines, instead of the wheels of the locomotive engine. The two crab engines perform the operation of driving the pile with a ram of the same weight, and in the same manner as those generally adopted for all the large works in this country, such as the coffer dam to the new Houses of Parliament and the bridges. With this machine two piles are driven at the same time.

In America the steam machine has been generally adopted for the construction of railways on piles, for which purpose it is well adapted, for as soon as the machine has driven a pair of piles, it cuts off the heads to a level, or with a slight inclination according to the *grade* required for the railway, and then rails are laid upon the top either with cross sleepers or not as may be desired; the engine advances forward another length and performs the operation again; thus one engine is enabled to drive two rows of piles at about five feet apart, one mile in a month.

The principal object of inquiry is to see how far this machine is superior to those in ordinary use, and as we just stated, in the steam

machine we have simply engine power applied instead of manual labour, for the working of two pile driving machines of the same magnitude and power as those in ordinary use. For this purpose it is absolutely necessary to make a series of observations and ascertain the number of piles that can be driven in one day by the steam machine, and the cost of labour, fuel and expenditure of capital, in comparison with the labour consumed in driving the same number of piles by the ordinary machine. At present, our materials do not warrant us in offering any opinion, but we shall hereafter attempt to obtain some information regarding this very important part of the inquiry.

For the steam machine, it requires to work the engine and apparatus for driving two piles at one time, with a ram weighing 16 cwt. the following men;—an engine-tender, one man for throwing each apparatus in and out of gear, and one man to attend to each pile, making altogether five men for driving *two* piles. For the ordinary machine it requires four men to work the crab engine for lifting a ram of the same weight, and one man to attend to the driving of the pile, making five men for *each* pile, or 10 men for two piles. With the steam machine the ram is lifted four or five times in a minute, thereby the operation of driving the piles is very short in comparison with the ordinary machine. The cost of the steam machine with an engine of ten horse power, tubular boiler and apparatus is about 700*l.*, and the cost of the ordinary pile driving machine with crab engine is about 70*l.*

The following is a description of the American steam pile driving machine, and the operations for which it is applicable.

The machine consists of two pairs of leaders, similar to the common hand machine, placed 6ft. from centre to centre, (the common American railway gauge), and firmly bolted to a strong horizontal framing, and supported by two oblique ladders. The frame is 9 feet wide to the outside of the framing, and 28 feet long, it carries at one end a locomotive boiler 11 feet long and 2 ft. 6 in. diameter, calculated to bear 120 lb. per square inch pressure, but generally worked at 80 lb.

per square inch, and about 100 strokes per minute. Under the boiler is placed the supply cistern. In the centre of the framing, and on each side of the boiler is a pair of inclined cylinders $5\frac{1}{2}$ inch bore, with solid pistons working well without packing, and 14 inch stroke, which act on right angled cranks; and the gearing, drums, &c., described in the motions of the machine; the shaft centres are 1' 3" apart, the spur wheel has 56, and pinion 19 teeth; bevels 101 and 40 teeth; saw pulleys 1' 9" and $10\frac{1}{2}$ inches diameter. The ram is generally raised from 4 to 5 times a minute, the steam being at 80 lb. per square inch.

For river work the machine is made much more compact, the apparatus is placed on each side and over the boiler, so that the stage is little more than half the length of the machine shown in the engraving, and it is also sometimes made with an apparatus for driving one pile only, consequently requiring smaller power.

In the drawing, fig. 1 is a side elevation of the machine; fig. 2, elevation in front of leaders, showing saw, &c.; fig. 3, a section taken in front of gearing, &c.; fig. 4, a plan of gearing end, with leaders and ladders removed, and showing saw in plan, similar letters refer to similar parts in each figure.

Taking up the pile.—The ram A being secured by placing the stop B under it, by means of the small ropes attached to the latter, and passing over the small pulleys C C, to within 3 feet of the stage. The dogs D are made fast to the pile (fig. 3), the rope attached to which passes upwards through the small guide pulleys, and over the outer pulley E, passes downwards and is coiled round the pulley F, fixed on the shaft G, which being made to revolve, raises the pile to its place between the leaders, and is then secured by the loose stay H, and the iron work H' placed round it for guiding it perpendicularly.

Driving the pile.—The stop B being withdrawn from under the ram A, the ram is raised by a rope, which being secured to a staple on the top journal passes down under the pulley I, then upwards over the pulley K, and again downwards to the drum L, upon which the rope is coiled, the drum is placed on the shaft G, which is made to revolve by the spur wheel N, working in the pinion O, on the lower shaft P, which shaft revolves by the action of two cranks Q (Figs. 1 and 3,) placed on each end of the shaft P, the cranks are set at right angles to each other, and are worked by the connecting rods R, attached to the piston rods, which are furnished with slide parallels as shown in fig. 1. The slide valves of the piston are worked by the eccentric V, on the end of the shaft P. Steam is supplied to the cylinder by the pipe S, from the boiler T; the boiler is supplied with water from the cistern M, (fig. 1) by the pump W, which is worked by the eccentric rod X, fixed on the spur nave at Y, or by the handle at Z; the supply of steam is regulated by the handle (a) acting on a valve in the steam pipe (S). The drum L consists of a fixed and a loose cylinder, the latter revolving by the friction of the former (fixed), and is brought into or out of contact by the hand lever (Y) figs. 1 and 4, which has a fulcrum attached to the standard.

The follower f' is furnished with a pair of tongs or clippers, which takes hold of a staple fixed in the ram, and carries it to the top of the frame; then when the top of the tongs is pressed closer together, by coming between the contracted checks e' e', the lower part opens and allows the ram to fall.

For working the apparatus the engine-tender stands at the valve S, and a man at the lever y of each machine. For raising the ram the man turns on the steam at the valve S, which sets in motion the apparatus of each machine, and coils the rope round the drums, at the same time raises the ram, as soon as the latter reaches the top of the leaders, the ram is detached and descends, at the same moment the engine-tender turns off the steam, and the men at the levers y throw the drum out of gear, which allows the clippers and chain to descend again and lay hold of the ram; when the drum is again thrown into gear, the steam turned on and the ram again raised, and so the operation is continued until the pile is driven.

Drawing a pile.—Chain tackle is secured to the pile and passed over the top pulley to the drum L, and is then drawn by applying the power to turn the drum of the apparatus.

The Saw Apparatus consists of a circular saw b, 4 feet diameter,

having teeth set 3 inches apart, secured to the end of a beam c, which beam works on the upright shaft d for a centre, and slides laterally on the iron arc e; when used the saw is adjusted to the proper height by the screws f, and a bar having a hook in one end and fitting into a staple in the beam's end, is used to press the saw against the work, the bevel pinion g being raised into gear by the foot lever h, (fig. 4), motion is given to the pulley i and j, and band k, which work the saw b. The operation of sawing off the end of a pile takes less than a minute.

Progressing motion.—The hook l being fastened to a driven pile, and the rope passed over the pulley m attached to the side of the frame to the pulley F, round which it is coiled twice, and the end held by a man—motion being now given to the drum, the machine progresses—this motion is shown by the dotted rope fig. 1, it should be stated that the frame is intended to be supported upon six railway wheels, which run on a temporary rail laid on the top of the piles as they are driven. There is another mode of progressing, but which is not found to answer so well, viz. by means of two sledge beams faced with iron and attached to the under framing, these are placed six feet apart from centre to centre, and pass under the whole length of the machine, and slide on small iron wheels fixed to standards, which are placed loose on the piles.

The plumb-bob l suspended to a line regulates the pile being driven perpendicularly, and Y is a lever attached to a friction band break passing over the end of the drum, which is only used occasionally.

It is remarkable that writers on mechanics have not been able to agree on the precise manner in which the force of the blow given by the ram of a pile engine should be estimated, and the question appears to have been greatly confused by confounding it with the effect produced in sinking the pile. Now it is one thing to estimate the force of a blow, which is simply to determine the weight which, acting by pressure alone, will produce the same effect as the blow, and it is another thing of a widely different nature to determine what that effect actually is. Any practical man at all acquainted with the nature of pile driving, will at once scout the idea of being able to establish the law, according to which a pile will actually sink by successive blows of the ram; because it is well known that the sinking of the pile is by no means regular or proportioned to the friction opposing its descent as determined by theory. On the contrary, in defiance of all theory, a pile will sometimes sink more at the 4th or 5th blow, than at the 1st or 2nd, or perhaps more at the last blow than it did 10 or 15 blows before; and yet it is obvious that if we were attempting to investigate theoretically the resistance of friction, we must estimate this resistance to increase in some regular proportion to the depth to which the pile is buried in the ground.

Practice, however, shows that occasionally the resistance is less than at a previous blow, when theory would point out that it is more. We therefore reject from our consideration every attempt to determine the actual effect produced by the force which we are able to exert on the pile. In fact, whether the blow produce any effect or not, the force exerted is still the same, and this is all that theory can determine, because the sinking of the pile depends on conditions of tenacity and consolidation of the ground to be driven into, which are too various and complicated ever to be capable of general expression in the formulæ of calculation.

It is true that Belidor and other French engineers, in that ardent spirit of investigation which leads them to build up theories on a purely hypothetical basis, where a practical or experimental one is impossible, have assumed the rate of consolidation of earth at each successive foot below the surface, and then taking into account the surface of the pile exposed to friction, have attempted to estimate the rate at which the pile would sink with each blow of the ram. We doubt, however, whether practice would ever be found, in a single instance, to confirm a theory so established; at any rate we should esteem the coincidence of the two almost miraculous, even if, in some rare instance, they ever have agreed.—Apart, then, from all consideration of the effect produced in sinking the pile, let us simply enquire

the actual force with which the ram, in falling from a given height, strikes the head of the pile. Obeying the law of accelerated velocity, the ram will fall through any space s in the time $\sqrt{\frac{s}{g}}$, where $g = 16\frac{1}{2}$ feet, the space through which a heavy body falls in one second of time. Now it is a fixed and well established rule in mechanics, that the velocity acquired by falling through any given height is proportionate directly to the time of descent, and that the velocity acquired at the end of the first second of time is equal to $32\frac{1}{2}$ feet per second; hence it follows that the velocity acquired by a body in falling through the space s is equal to $32\frac{1}{2} \sqrt{\frac{s}{g}}$. Then to find the force

of the blow, the weight of the body is to be multiplied into this acquired velocity, which it must be understood is not the velocity with which the body has fallen, but the velocity in feet per second with which it would fall during the next instant of time, were it not suddenly stopped by striking the pile.

According to this formula, the following table has been calculated, showing in one column the time of descent in seconds of any ram falling from 1 to 40 feet, and in the other, the force in tons with which a ram weighing one ton will strike, in falling from the same height.

Fall of Ram in feet.	Time of Descent in seconds.	Force in tons for a Ram weighing one ton.	Fall of Ram in feet.	Time of Descent in seconds.	Force in tons for a Ram weighing one ton.
1	0.25	8.0	21	1.14	36.7
2	0.35	11.3	22	1.17	37.6
3	0.43	13.9	23	1.20	38.5
4	0.50	16.0	24	1.22	39.3
5	0.56	17.6	25	1.25	40.1
6	0.61	19.6	26	1.27	40.9
7	0.66	21.2	27	1.29	41.7
8	0.70	22.7	28	1.32	42.4
9	0.75	24.1	29	1.34	43.2
10	0.79	25.3	30	1.37	43.9
11	0.83	26.6	31	1.39	44.6
12	0.86	27.8	32	1.41	45.4
13	0.90	28.9	33	1.43	46.1
14	0.93	30.0	34	1.45	46.8
15	0.96	31.0	35	1.48	47.4
16	1.00	32.1	36	1.50	48.1
17	1.03	33.1	37	1.52	48.8
18	1.06	34.0	38	1.54	49.4
19	1.09	35.0	39	1.56	50.1
20	1.11	35.9	40	1.58	50.7

The force of the blow given by a ram of any other weight than a ton may be ascertained from this table, by simply multiplying the number in the column headed "Force, &c." by the weight of the ram. Thus, if it be required to determine the force of the blow given by a ram of 16 cwt. falling from a height of 30 feet, opposite 30 we find the tabular number 43.9, hence $16 \times 43.9 = 702$ cwt. = 35 tons 2 cwt. the force required. This is the greatest force of the blow which can be given by the steam pile-driving machine described in our present number, the error formerly made of stating the force of the blow at 600 tons was on the authority of one of the foremen superintending the engine, and we take the earliest opportunity of correcting a statement so exaggerated.

The annexed diagram is intended to represent, by means of the curved line fff , the law according to which the force of the blow increases with the height from which it falls. For example, the distance ax measured on the horizontal scale will be 42.4 tons, the force with which a ram weighing one ton strikes when it has fallen from a height of 28 feet. The peculiar curve here shown is the result of that law by which the forces vary as the square roots of the heights from which the ram falls. If the forces varied directly as the heights, the straight lines bb would express the law of their increase, and if they varied

as the square of the heights, a supposition which, erroneous as it is, has been entertained by some persons, the law of the forces would be expressed by a curve of an entirely different nature from the true one, namely by the curves $c c$, according to which, if $e d$ were the force for a height of 5 feet, $e e$ would be the force for a height of 10 feet. The straight lines and the curves $c c$ are of course both erroneous, the true scale for measuring the forces being afforded by the curved line fff , so that the distance ax of any point x from the vertical line $A A$, measured on the horizontal scale $S S$, will give the force of the blow correctly in the same manner as the table.

THE LIVERPOOL PAVILION.

Erected at Liverpool, July, 1841, for the Great Dinner of the Royal Agricultural Society of England, under the direction of J. W. WILD, Esq., Architect.

THE object of this dinner is to afford an opportunity to the members of the society, assembled from all parts of the kingdom, of hearing persons eminently connected with agriculture and scientific men, speak upon points of special importance to them. The pavilion requires, therefore, no decoration, as it would for a festive occasion; all that is wanted is that it should be convenient for seeing and hearing the speakers, and for serving the dinner, and that it should cost the Society as little as possible.

The plan of the Pavilion at Liverpool, as shown in the annexed engravings, is a polygon of 24 equal sides, the greatest diameter between the opposite angles being 171 feet; within this space was provided accommodation for 2850 people, allowing 1ft. 8in. by 3ft. 9in. to each person, besides the main passages, which were four feet wide, and the committee-room and butteries. The staircases, 8ft. 6in. wide, were outside the building. A portion within this figure being cut off to form the offices, the remaining space for the seats was nearly the form of an ancient circus; the arrangement also was similar, as there were no galleries, the seats rising in steps around, and following the line of the outer wall. In order to bring the President's and Vice-President's tables nearer to each other, the high table was advanced from the wall some distance towards the centre of the building, thus leaving some few seats behind the high table.

There were six entrances into the body of the Pavilion, two upon the ground, leading into the pit, two above these into the upper seats,

Fig. 1.—Elevation.

and two other staircases leading also to the upper seats, and there was a private entrance into the committee-room and the platform.

As the dinner was cold, the first part of it was served upon the table before the guests entered, and from the position of the butteries and pantries, the waiters found it easy to serve anything wanted afterwards.

The roof of the building was supported upon its outer wall, and upon two ranges of 12 columns each, one within the other; the disposition of the roofs and columns being symmetrical with the arrangement of the seats, the sight was but very little hindered by these few supports, which were posts, 12 inc. square, with the edges chamfered.

Fig. 2.

Plan of Seats.

Plan of Roofs.

REFERENCE TO PLAN.

A. Committee Room. B, B, Buttery. C, High Table for President, &c. D, Vice President's Table. E, Pantry. F, Passage to Upper Seats. G, Passage on the Ground to Lower Seats. H, H, Staircases.

The entire covering was divided into three roofs, one within the other. The centre roof, 72 feet in diameter, was a pyramid of 12 equal sides, the apex was 40 feet from the floor; the base or top of the posts supporting the wall plate was 29 feet from the floor. The construction was 12 rafters, forming the angles of the pyramid, each (13in. $\times$ 4in.) abutting against each other in the centre, and secured there by a star-shaped strap of half inch wrought iron, each leg of which, 1ft. 2in. from the centre, was bolted to each rafter; the other ends of these rafters were secured and prevented from spreading, by connecting the wall plates with strong wrought iron straps, each two feet long, and forming thus a hoop round the base of this roof. The

ends of these rafters were also bolted to the upright posts. Light was admitted through a space round this roof under the wall plate; the purlines supporting the oil cloth covering were laid upon these principal rafters.

The middle division of the covering between the outer and inner range of supports was divided into 12 gable roofs, as their ridges were level, and all tended to the centre; the valleys formed by the sides of these roofs meeting each other, rise towards the centre, and thus easily carry off the water. No ties were required, as the rafters of each division abut against each other on the valley pieces, which, supporting a considerable weight, required trussing; the trusses used for these valley pieces (13in. $\times$ 4in.) was an iron rod $\frac{1}{2}$ in. thick, bolted to each end of the piece, and an oak wedge being forced between this rod and the underside of the beam formed the truss.

The gable ends of these 12 roofs also admitted light, and being under trusses, their tiebeams formed a continued line of support to one end of the rafters of the beam to the roof; the other ends of these rafters (averaging 17 feet long) are supported on the outer wall, this lean-to roof round the building, being the third or outer division of the whole covering.

It is to be remarked that within the space included by the covering, there is not one horizontal or isolated tie.

The material used for the covering was floor-cloth, prepared only on one side; it was returned to the maker after the building was taken down; the floor of the Pavilion was supported on 9in. brick walls, the outer enclosure was faced with the outside slabs, sawn from timber; the average height of which was 15 feet from the floor. Light was obtained through the gable ends of the roofs, and the upright portion of the centre roof, all of which were enclosed with white calico.

Mr. Wild's plan, with a model explaining it, was submitted or tender, together with the drawings, &c., of another plan previously executed for the society; this other plan was a parallelogram 113ft. $\times$ 197ft. offices attached 14ft. $\times$ 84 ft. The covering was a series of lean-to roofs; the accommodation offered by both plans was equal. The tender for this plan was £1225; for the plan adopted at Liverpool £1115; this difference of expense may be accounted for by the quantity of external enclosure being much less in the Liverpool plan, owing to the greater capacity of the figure; and as each of the 12 divisions of the plan is exactly repeated, without any curved lines and very little cutting, the construction is very simple. The principal waste was in the covering of the centre roof. As no ornament was attempted, the effect of the building was rude and naked, but the great multitude of people in still widening circles around, had a grand effect. As the plan was symmetrical, architectural decoration could have easily been given had it been required.

The position of the building was very disadvantageous for hearing, it being in a very noisy part of Liverpool: indeed, if, on the day of the dinner, a space around had not been covered with refuse bark, nothing could have been heard.

There was no echo perceptible in the building, the voice seemed to spread and lose itself as in an open yard. It was generally agreed that those who spoke clearly and articulately were well heard. For instance: Lord Stanley made a long speech, and seemingly without any great effort or loudness, and every word was distinctly heard in all parts.

The building, with its covering, remained standing altogether about six weeks; it was exposed to some very severe weather, but showed no sign of weakness any where. It was erected by the well known and respected builders, the Messrs. Holmes of Liverpool, whose execution of the work gave general satisfaction.

The Gorgon Engines.—We have seen a set of drawings of these engines, prepared by Mr. Jermy, for presentation to the Model Gallery, Somerset House, which do credit to the public spirit of the engineers and the skill of the artist. They show fully how the most practical subjects when properly treated become objects of beauty. We should like much for every engineer to present such records to public institutions, where they may be studied by the profession.

ON BEAM AND DIRECT ACTION ENGINES.

GORGON ENGINE.

BEAM ENGINE.

SIR—I am induced to address you from having read, in a contemporary work, a review of Mr. Scott Russell's publication on Scotch steam navigation, wherein concise mention is made of the engines termed "Gorgon," so *scientifically* named from their having been first fitted on board a vessel of that name.

Giving unto the manufacturers of these machines great credit for their general talents and ingenuity, and having a high opinion of their ability, I nevertheless, with reference to this particular case, have great doubts of the correctness of their title either to *originality in introduction*, or to any credit in *conception* or invention. I trust also that these gentlemen will not consider me to be actuated by any unfriendly motives; some of the published statements and assumed facts seem to me to be a little overcharged, and my desire is to induce explanation, and, by controversy, establish in your pages a conclusive and convincing account of all the properties of the arrangement, and at the same time, by comparative data and drawings, show its prefer-

ence or defect over other plans, more especially to the common beam, or Boulton & Watt marine engine first fitted on board the "Favorite" Margate steamer, in 1818.

It must be in the knowledge of most of your professional readers, that engines having a "*direct action*" were common many years ago, and it was not until the novel arrangement of the "Favorite's" engines became generally known, that they were put aside; since then the beam engine has reigned triumphant, to the *partial* usurpation of the Gorgon; it is my object to show the said "Gorgons" are not entitled to the position they may be said to have attained in the *royal navy*.

In the year 1822 a vessel was built at Leith, and was named the "Tourist;" her engines were of the "*direct*" kind, designed and manufactured by Mr. GUTZMER, also of Leith, and were, I may safely say, the *first ever made* for marine purposes. The arrangement was very like Mr. Penn's oscillating engine; the cylinders were of course

fixed, having *one* air-pump worked by a crank in the middle shaft; the condenser was a circular one, fixed before the air-pump in the middle line of ship. The cylinder was 40 inches diam. and 3 feet stroke, equal to a power of 40 horses, the space occupied was 10 ft. 9 in. in the fore and aft direction, and 11 ft. 6 in. athwart; the vessel was low, and the paddle wheels being *proportioned to the stroke*, the connecting rods were *short*. The piston rods were fitted with parallel motions.

Thus, so far as the *direct application of the power goes*, the engines of the Tourist, Gorgon, Cyclops, &c., are *identical*. I therefore must object to the Messrs. Seawards' nomenclature, it should be "Gutzmer," not "Gorgon."

In 1826, Mr. David Napier completed his splendid ship, the "United Kingdom." The engines were upon the direct principle, with, I conceive, considerable improvements; these consisted of separate condensers and air pumps, in a half side beam, an additional crossbar, and *side rods forming a connecting rod*, by which means this latter was *doubled in length* to what it would have been on the Gutzmer principle. I cannot give the exact space occupied by these engines, but feel assured that with equal powers and capabilities, they have the advantage over the Gorgons.

Having explained my objections to the claims of the Gorgon engine on the ground of originality, I now come to its *intrinsic* value as compared with its competitor the beam engine, and I beg to premise that I use the term "competitor" in a *Royal Navy* sense only, for I believe I am correct in stating that, with the exception of the Russian Emperor and Mexican Government, that this government is the only patron of the Gorgon engine. I mean to say that it is entirely excluded from the *vast* commercial marine of this country. I think I may also say entirely from France, but I am open to correction on this point; at all events, the former fact shows plainly, that *if* it has no defects, it at least has not the advantages which are claimed for it. I may observe, with reference to the value of government patronage, and I merely state a plain and well known fact, that they are far behind private knowledge and enterprise.

In a pamphlet published by Messrs. Seawards & Co., the following statements are made, and a drawing given of the Gorgon's engine; of the latter's accuracy I have no doubt. I dispute the former. They say, 1st, they occupy $\frac{1}{2}$ less space, and weigh $\frac{1}{2}$ less than the beam engine. 2nd, that there is less friction, consequently less wear and tear and loss of power. 3rd, that the consumption of fuel does not exceed 6 $\frac{1}{2}$ lbs. per horse power nominal per hour. I purpose taking these as they stand. 1st, the space occupied by the Gorgon and the beam engine can only be shown by a drawing; such accompanies this letter, sketched to the same scale, and placed relatively to each other. The upper is that of the Gorgon, as copied from the above-mentioned pamphlet, the lower is of a beam engine, in sketching which I have not followed the "architecture" of any manufacturer, for obvious reasons, having no professional object in view.

You will therein see that the base of the Gorgon's engine is 20 ft. 6 in. long by 7 ft. 10 in. wide, that of the beam engine 20 ft. 9 in. long by 8 ft. 6 in. wide over the main gudgeons or widest part, being in excess, *three inches* in length and *eight inches* in width only! This is an astounding fact, and before publishing this paper (if it is doomed to such fortune), I beg, Mr. Editor, that you will carefully look to this point, and test its accuracy; I believe it is fair and honest, and, if published, will speak for itself. So much for the boasted Gorgon engine, $\frac{1}{2}$ less,—'tis a hacknied phrase. It does not appear that any claim is made for improvement in the boiler. I have a drawing of the Cyclops'; they are of the common construction, single flue (that is, all on one level) having fires at both ends; they are across 19 ft. by 31 ft. fore and aft, and 8 ft. 10 in. high; this is all common-place. I have therefore no remark to make until I speak of their weight, and the reported consumption of fuel.

I now come to the *weight* of the Gorgon's machinery, and premise that this is a point of great importance, as I have reason to think its reported *small amount* was ONE of the principal causes of the introduction of these engines into the navy of Great Britain.

The engines were stated to the government to weigh 121 tons.

Paddle-wheels	24
Boiler	64
Water in Boilers	48
	257 tons.

A total of 257 tons omitting the coal boxes.

The weight of a pair of beam engines of 320 horses power of most approved construction, with boilers, paddle-wheels, *coal boxes*, and water in boiler to working height, would not be more than 290 to 300 tons, but say the latter, to put the question on its broadest base, that is .93 of a ton to a horse, which you will find a very ample allowance. Supposing the 257 tons to include coal boxes (although not enumerated) we have a saving of $300 - 257 = 43$ tons and $\frac{43}{240} = \frac{1}{6}$ saving by the use of the Gorgon's engines! really, Mr. Editor, this appears "too bad." Can the statement of $\frac{1}{6}$ saving be made on honourable principles, or were the manufacturers so far carried away by enthusiasm as to *slightly* exceed the bounds of truth?

A few words more on this subject; I have reason to doubt the accuracy of the total weight given to the Admiralty, viz. 257 tons. The following has been handed to me by authority on which I can rely. It may be said it is merely an anonymous statement. Granted; but I am ready, Mr. Editor, to give you the name of my informant (in confidence), and you shall be the umpire as to its value.

Corrected weight of Gorgon's engines will stand thus;—

	Tons.	cwt.	qrs.	lb.
Engines	123	3	0	13
Paddle-wheels	40	0	3	24
Boiler	68	17	2	5
Chimney	6	3	3	6
Coal Boxes	20	2	1	18
Water in Boiler	40	8	0	0
*Total	298	15	3	10

I say I believe this to be correct, and leave your readers to form their own conclusions, or to make further enquiries. All I can say is, that it calls loudly for explanation.

I proceed to the second subject "That there is less friction in the Gorgon's engines, consequently less loss of power, wear and tear, &c."

This I consider to be merely professional, and fear my inability to make myself fully understood by casual readers; however, avoiding all scientific observation as to the "laws of friction," I shall merely point out the parts generally included in the beam but avoided in the Gorgon engine, and allow your readers to draw a common sense deduction as to the saving in this particular.

The following are common to both constructions: the pistons, air pump buckets, hot and bilge water pumps, shaft bearings, crank pins, &c. The connecting rod bearing on cylinder cross bar of Gorgon, is equal to the beam engine connecting rod cross bar; in this latter we have the two main gudgeons, the air-pump gudgeons, the side rod gudgeons, and the parallel motion, to be balanced by the rocking beam and parallel motion of the Gorgon engine; and although last, not least, the enormous friction on these parts caused by the short connecting rod, and which I am assured is so great as to equal $\frac{1}{2}$ the power of the engine passing through them to sustain the piston rod to move in a perpendicular line.

On this point I am content, that those who are cognizant of the parts of both engines, or can judge from the drawing given, may form their own conclusions.

3rd. That the consumption of fuel does not exceed 6 $\frac{1}{2}$ lb. per *nominal* horse power per hour.

Nothing can be more absurd than to draw any conclusions from the consumption per nominal horse power, the merest tyro in the profession must be fully aware that in the same engine (or generally speaking in engines from the same manufactory), the consumption of coal *will always be as the work done*; it matters not how you may turn and twist

* We must observe that this weight includes chimney and coal boxes, not included in the before-mentioned weight of 257 tons.—EDITOR.

this fact, it is still so; by loss on the slide valve you save steam, but you reduce your power* in the same proportion; and was moderate consumption of fuel the only desideratum it is easily obtained; you may save coal by not using steam, and that is simply done by preventing its ingress to the cylinder. Thus actual power is reduced, but nominal power is fixed, and hence the result of $6\frac{1}{2}$ lb. consumed on board the Gorgon.

I may here incidentally observe that a good marine engine should exert an average pressure on the piston of 14 lb. per square inch, and this exclusive of all friction of the moving parts; this, according to Mr. Watt's computation is just double the nominal power. If under these circumstances it consumes 9 lb. of coal per nominal horse power per hour, or $4\frac{1}{2}$ actual horse power, you may be content. I have known this exceeded, but think it rare; a pressure of 16 to $16\frac{1}{2}$ lb. on the inch is common in these days, and that with a boiler pressure of 6 lb. Therefore to form a fair experiment of the consumption we ought to be favoured with an indicator figure, showing the average pressure, with the speed of the piston per minute.

The Gorgon's cylinders are 66 inches diameter and 5 ft. 6 in. stroke, and according to Mr. Watt's computation, (I take his data as I consider it beyond cavil), should make 20 strokes per minute, or 220 feet, producing a power of 160 horses, or 320 for both engines. This is just equal to 18-57 cwt. per hour, is this fact? I put it Sir, to your own knowledge, as well as to that of your general readers.

One other point only remains to be considered, the actual speed of these Gorgon's engines. I am told in consequence of the great immersion of the Gorgon, her engines seldom make more than 14 to 15 strokes per minute, if this is true the mystery is solved, the consumption of coal is increased at once in the proportion of 20 to 14, equal $9\frac{1}{2}$ lb. per nominal horse, about the usual thing supposing the actual power double as above stated.

Of the "Styx" I can speak with confidence, on her trial in the river, with my Lords and a large party on board, with coal enough for the trip, no masts, stores (except, to the credit of the engineers be it said, no mean supply of the very good things of this world), guns, &c., at her light draft she made 17 strokes per minute, and when loaded it is reasonable to suppose the increased resistance would reduce that two or even three strokes per minute at least; therefore how utterly inconclusive it would be to form any judgment as to the consumption of coal upon such data. No, this may do for the government folks, but the steam public will require deeper investigation; let us have an indicator figure, the number of strokes per minute, the speed of vessel with her immersed section, and then we shall be enabled to see if modern ingenuity has done more than old "Gutzmer" did in the "Tourist."

There are other defects attached to the Gorgon engine which deserve notice. It has been frequently observed, even by unscientific persons, that in the "beam engines" every part was beautifully adopted to its purpose, and was so well balanced, that disconnected from the shaft it preserved its position, it results that its motion is equable and smooth, with a minimum friction on the moving parts. Although I differ from those who suppose there is a mechanical loss of power in the use of the short connecting rod, still I conceive the most sanguine supporter of the "direct engine" must allow there is a loss of power from attendant causes, the undue friction thrown upon the parallel motion upon the shaft bearings and other parts, in consequence of the oblique action of the connecting rod, and more than all the irregular motion arising from the weight of the pistons, connecting rods, cranks, cross bars, &c. being totally unbalanced, except by the paddle wheel, which I consider so rude as out of the pale of civilization, and which, by the bye, cannot be carried into effect when any apparatus is fixed for disengaging the shaft, as the paddle wheel would not revolve, the very end to be obtained by such device.

* The writer of this paper does not think it necessary to explain the theory of expansion, to show that the power lost by it is not in proportion to the steam saved, nor is it worth while to show that the speed of the ship would be reduced as the cube roots of the lost power, his desire is to prove the unsoundness of reasoning upon nominal horse power consumption.

Another disadvantage is that in order to get a moderately long connecting rod, you are obliged to construct your paddle wheel much too large in diameter for the stroke of the engine, and in order to reduce your resistance, to contract the length of the board; this applies to all our Government vessels hitherto fitted with direct engines, and in fact to this I principally ascribe their low speeds.

Puffing is a horrid resource; I have been amused to see the manner in which the Gorgon and Cyclops were brought before the public on the recent bombardment of the Syrian coast; surely this is unfair and not national. The Phenix, Medea, Hecla, Hydra and many others did their duty, which I presume is all the first named were called upon to perform.

One observation more, and I fear I am only disseminating a generally known fact, that the great majority of our war steamers have very low velocities. I know not what other countries possess, but this must be evident to all, that (putting aside great disparity of force), the fastest steamer will be the conqueror, and thus as in the American war, our noble tars will be sacrificed to the miserable inefficiency of those who have the governance of such matters.

I conclude with a prophecy. Fashion must have its course in steam as in other matters, but ere long we shall come back to the scandalized "Beam engine." The Gorgons may shake their heads, and Cyclops wink their "central orbs," they will meet the fate of the "Tourist," now propelled by a pair of beam engines. Like in the paddle wheel mania, we gyrate from poor Buchanan who "shone" in 1814, through a vast series of minor inventors down to Morgan, who went out in 1838 or thereabouts;—this is all very well, and is good for trade, but who pays?

I remain, Sir, your's truly,

VULCAN.

London, December 9, 1841.

ON THE USE OF GOLD IN DECORATION.

SINCE architects are beginning to pay more attention than formerly to the minor parts of decoration, it may not be venturing out of their province to turn their attention to a very important branch of it—though it is ground on which, from being confined by the impregnable laws of fashion, it is more dangerous to tread than even the slippery path selected by Mr. Bartholomew. When we have designed our decoration with the greatest attention to harmonious colouring, taking care that each may have its proper proportions, and making a cautious use of bright colours out of regard to those which are more subdued—the artist comes, and to the injury of his own works, as well as those of the architect, covers the wall with a phalanx of rich gold frames of precisely the same character, whatever may be the tone of the room or the nature of the picture. If the statements of Mr. Clarke be correct, that yellow is to be used with great caution and never in large quantities, and it undoubtedly is correct, and is universally allowed to be so, except in this one point, it surely is contrary to every principle of colouring, either in decoration or the management of a picture, to introduce this dangerous material in a manner entirely regardless of surrounding or surrounded objects. Pictures of the most delicate as well as the boldest character have frames to match each other rather than themselves—and this because no one has the courage to propose a remedy. Artists are not much afraid to intimate with caution that the talon-like form in which the finger nails are suffered to luxuriate, has no authority in the antique. Some one more hardy than the rest, suggests to a lady that if her daughter's waist was really pinched as small as she wished it to be represented, "she would not be alive a minute." But the other practice is too finely paid, for any one to attempt its removal—though we must not despair of time effecting what no other less potent agent can. Equally absurd and deeply rooted fashions have given way. It has been discovered that the human form is seen to more advantage in a simple garb, than when the upper extremity appears emerging from a gigantic cheese. And possibly it may be found that works of art, more precious than diamonds, like

them do not require to be set in gold. We have Sir William Gell's authority, than whom no one had a better opportunity of studying internal decoration as practised by the ancients—that the suggested innovation would be in accordance with the principles of those whom we profess to follow and admire.

If the space taken up by frames at the Royal Academy were occupied with some quiet separating colour, the pictures being surrounded with simply a gold moulding, we should not hear so many complaints of the killing effects of the exhibition to all pictures that are not painted after Turner's manner. Gold in large quantities will some day assuredly be banished from the picture gallery, to situations where it is required as an architectural decoration, and where it will therefore be subjected to the disposal of the architect instead of to that of the frame maker.

J—L.

AN APPARATUS FOR DISCONNECTING THE PADDLE WHEELS OF STEAM VESSELS FROM THE ENGINES.

By MR. GRANTHAM, North Foundry, Liverpool.

To effect the connection and disconnection of the paddle shafts of steam vessels, has been the subject of many ingenious plans, but we have not seen any which appear better calculated for this purpose than that of Mr. Grantham, a description of which we now give.

The parts of the annexed diagram marked 1, represent the paddle shaft of an ordinary marine engine, 2 the intermediate shaft, and 3, 3, the cranks by means of which the engines are made to revolve. This new contrivance consists in having in the eye of the exterior

crank, a sliding brass step A, which may be moved in either direction by the screw C. The screw to be worked by a ratchet spanner on the square end F, and to be of such pitch that one revolution for small vessels, and two for larger vessels, will be sufficient to effect the operation.

The sides of the brass step project unequally, as at G and H.

For Disconnecting.—The brass step is drawn back by the screw C to allow the crank pin to pass clear.

For Connecting.—The brass step is moved forward one or two inches, so that the crank pin can pass the side G, but comes in contact with H. The correct position of the several parts being thus determined, the brass is screwed out to its full extent.

TILE MACHINE.

New Patent Invention for the Manufacture of Draining and other Tiles and Bricks. By WILLIAM IRVING.

The advantages of the machine exhibited in the annexed engraving are its simplicity and cheapness in its construction and working. It is stated by the Patentee that by the labour of one man and three boys, 5000 tiles per day can be made with ease, at a cost of less than 2s. per 1000. At one operation 16 tiles are made, which an experienced hand would accomplish in one minute, equal to 9,600 per day of 10 hours.

The machine is so portable that one man can carry it, and needs no fixing.

The machine may be seen at work at Richmond Wharf, Nine Elms, London, every Monday afternoon.

The process of making tiles by this machine, is as follows: a quantity of material sufficient to fill the box, or mould, is thrown in as in the ordinary process, and the surplus cut off even with the top, by a scraper of any convenient form or material. The end DD, and the frame or hoop FF, are then removed, and the workman (who stands at the end Z of the machine) takes the cylinder H H by the handles, and raising it up vertically, rests it upon the top of the box, or mould, with the rings, or guides aa upon the said cylinder outside, or against the outer face of the sides B C, thereby causing the wires attached to the cylinder H H to be brought against the face of the material left exposed by the removal of the end D D. The cylinder H H is then drawn along the top upon which it rests, and the wires are made to pass through and cut the material into the required number of tiles, according to the arrangement of the wires upon the said cylinder H H. The wires are thus brought through the material to the cuts or openings in the end E E, and over the roller L L in the grooves of which they are received and left.

The material being now completely separated into the required number of parts, the side B is laid down upon the table or bench A A (which is made wider at that end to receive it), the board G G, with the material upon it, is drawn out between the guides J J, and the tiles are taken to be horsed or otherwise, as may be expedient.

ON COLOUR AS APPLIED TO DECORATION.

By HYDE CLARKE, F.L.S.

(Continued from Vol. IV. page 409.)

In the last volume I gave an analysis of the principal colours, and pointed out their several properties, reserving for the present occasion those observations which refer to the practical application of this knowledge in decoration, for which purpose I shall avail myself of the labours of Chevreul and Hay. The former writer has, indeed, treated the subject extensively and minutely; Mr. Hay, attaching himself to the elementary portion, which has been seriously neglected here, has only discursive notices scattered through his pages. A complete work on this subject is, in fact, one which yet remains to be written in English, although very much wanted, particularly at the present period, when attention is so much directed to decoration.

It has been before observed in the Journal, that there are two modes of composition, one in which boldness of effect is sought, and the contrasting or harmonizing properties of colours are made use of, and the other in which softness being the object, the architect or decorator avails himself of their melodizing properties. The next consideration after this in a regular composition, is the choice of a key colour, that is of the colour which is intended to preponderate in the arrangement, and to which all the others are to be adapted. Of course, in practice such a regular method can seldom be followed, and it is then that the ability of the artist is called into requisition to make the most of his materials. Limited as I am by the nature of the plan I have laid down, I cannot enter into this subject at any length, but it may be some guide to the student if I call his attention to some of the most glaring errors, which too often beset our artists, and upon which Mr. Hay so strongly dwells in his *Laws of Harmonious Colouring*. On the side of contrast these are the preponderance of some striking colour, or the deficiency of strength of the balancing colours; with regard to compositions in melody, we too often have to witness absolute monotony, or else the want of media to unite the leading colours employed. Another fault is confusion arising from inattention to the key colour.

Having dismissed these preliminary remarks, it will be our duty to consider the subject first as it regards decoration generally, and then as it concerns the several apartments, or as it influences the choice and arrangement of furniture. In the first instance we shall have to consider what is the aspect and the kind of light to be employed: for if we have the warm tones of the summer sun from the south and west thrown into an apartment, coolness must be preserved; but if we have a wintry aspect or morning light, recourse must be had to warmth of colouring. Where artificial light is used on a large scale, deep colours must be proscribed, and pure yellow, purple, green, and orange used with great moderation, all the former from being deteriorated, and the latter one because it becomes too glaring. Where rooms are lighted so that the direct rays of light are thrown entirely upon the floor, and the walls left comparatively in shade, a bright scarlet has been known to produce a good effect, the want of direct light preventing it from obtruding upon the eye (Hay, p. 51). In such cases, deep toned colours must predominate on the carpet, and gilding may be advantageously resorted to. If the artist has to consult the ladies in his arrangements, he finds that the tints of red, orange, and purple are all disadvantageous to the complexion, and that yellow, light green, or light blue, are among the more favourable, and then whitish and grayish tints. White may be advantageously used in decoration as a prevailing colour, when lowered in tone, and light marbles, gilding, sky blue silk, and satin wood furniture, used with it. Yellow, when pure, cannot be used in a large mass, but when lowered in hue is agreeable; when yellow is the prevailing colour, the tone of the accessories must be heightened, it does not agree very well with gilding. Red requires that the general tone should be warm, and cannot be used in large masses, although it is a good key colour. Bright green should not be used with it, but green, approaching more to an olive

tone, also russet and brown. Into such arrangements gilding may be introduced with happy effect. Blue, requiring coolness of character to be preserved, is a very advantageous colour, particularly when light; it agrees well with gilding and mahogany, but must not be used with pink. Orange is a good key colour, and although not a favourite, may be advantageously used; masses, however, must be avoided. It requires a warm tone. When used, blue must be kept subordinate to it, and this subordination in intensity ought to be in shade rather than in tint, or by neutralizing the blue by an admixture of a small portion of orange. In this arrangement black and white must be left out, russet, citron and brown should predominate, being occasionally relieved by the deepest shades of indigo (Hay, p. 47). A bright yellowish green agrees very well with mahogany and gilding, and with light tints of lilac or pink, and with it orange may be employed in small masses. Mr. Hay recommends with bright green, for any light, an arrangement of cream colour, French white, gilding on the cornice, ceiling and wood work, with damask hangings of giraffe and gold, and a suitable carpet. Where this arrangement is inverted, he says, when the hangings and chair seats are green, and the walls of a warm colour, the effect is equally beautiful in day light, but in artificial light it is injured. Bluish green requires a cool tone, as does gray. Crimson requires a warm arrangement, and on account of its good effect with gilding, is much used. Lilac and pink are considered to require coolness, and brown, warmth.

Directing our attention to the mode in which the uses of the several apartments guides the artist in his treatment, we should observe, that the drawing room being the scene of gaiety, vivacity and brilliancy should prevail, and that there the artist has his greatest scope. This vivacity, says Mr. Hay, is produced by the introduction of light tints of brilliant colours, with a considerable degree of contrast with gilding; but the brightest colours and strongest contrasts he recommends should be upon the furniture, the walls being kept in due subordination, but at the same time partaking of the general liveliness (p. 36). The dining room should be warm and rich, the furniture solid, and gilding not too prominently introduced. If coolness is wanted, as in a summer residence, blue may be made the key colour. A bed room should be light and cleanly, to produce which white and yellow may be used, and on account of the bed and window curtains forming a sufficient mass to balance tints of equal intensity on the walls, brighter and gayer colours may be introduced on the carpet, and a greater degree of contrast on the walls (Hay, p. 37). A library should have an air of repose, and yet a solidity of character; grandeur being produced by that amount of richness of colouring which is sufficient to banish monotony. With picture galleries, ornament and gilding should be sparingly applied as they tend to injure the effect of the pictures; for the walls, crimson, buff, and salmon are the tints that are preferred. In galleries of sculpture a pearl gray brings out the marble or plaster figures, although, if they are of a reddish tinge, the walls may be painted chamois or orange gray. Some sculptors like to produce a bright light on their figures, and then a grayish blue must be applied. Green has not a disagreeable effect, the statues taking a pinkish hue. For halls, vestibules, staircases, and lobbies, where breadth and extent are desired, coolness of tone must be preserved.

It will now be requisite to trouble ourselves with some few of the many details, in accordance with which the decorator has to combine his designs, or render them subordinate. For clearness I shall distribute the short remarks I have to make upon these subjects in distinct paragraphs, regretting that it is not in my power to enlarge upon them to a greater extent.

Stained glass can only be used with the medieval styles, and must not be mixed with plain glass; neither should the designs upon it be complicated. Engraved or embossed glass, when used on a large scale, has rather a dull effect.

Gilding cannot be used in every situation, nor combined with every colour, as yellow, but has a good effect with blue, light green, or crimson.

With regard to paper, as that forms the groundwork of the design,

sufficient has been said in the general remarks to require no further notice, except to point out the mischief which is done in choice of this as well as of other articles by the selection of patterns which, however good when looked at on a small scale, are obtrusive when forming a mass.

Hangings and coverings of sofas and chairs require great management. If the wish is to contrast them with the wood, purple or blue stuffs are of course used with yellow woods, and green stuffs with red woods. Bright red colours, as scarlet, &c., must never be used with mahogany, as they lower the tone of the wood, making it look like oak or walnut. Where gorgeousness or splendour is desired, the hues of orange, as gold or giraffe, do very well for window curtains, chair seats, &c. In silk, bright blue is very pleasing, and black is also effective in that material; with regard to worsted, however, although blue and its various shades are equally useful, black is very apt to be sooty and heavy.

As a room is never too light, and as the light may be diminished by blinds or venetians, and as at night-time artificial light is used, hangings should be of a clear and not dark colour, so as to reflect light instead of absorbing it. When used in masses the deep shades of all colours should be avoided, as absorbing too much light; red and purple as unfavourable to pink or lilac; orange, as before mentioned, from being too intense. Yellow, only, and bright blue and green, are really effective; yellow, as being gay and suiting mahogany, though not gilding, blue; as favourable to gilding, not injurious to mahogany, agreeing better with yellow or orange woods, although unfavourable to pink in day-light; green, as being advantageous to pink, and to mahogany and gilding.

Carpets have great influence in decoration, for in daylight they receive the rays of light more directly than any other part of the furniture and decoration. On this part of the subject Mr. Hay has many useful notes; he recommends that in carpets green should always preponderate, as it is most pleasing in daylight, and also relieves other colours, and harmonizes with them in its various hues, more generally than any other colour does. Its bright and vivid hues are easily neutralized, and seldom produce crudity or harshness of effect, while its rich and deep tones, especially when neutralized towards a tertiary hue, citron or olive, harmonizes with and give value to all denominations of warm colours. Thus far Mr. Hay; he further says that its cooler hues and shades ought to be used with more caution, for they are apt to appear blackish and heavy, although the blue predominates in them to the same extent that it does in the hues of purple called indigo, yet they have not the same clearness. In carpets, bright yellow, red, or scarlet should not preponderate, as they are apt to catch the eye, and so spoil every thing else which it afterwards looks at; black and white must be used with equal caution, and, indeed, at present their indiscriminate introduction is one of the greatest defects of the modern manufacture. In the finer specimens of Persia and Turkey we find the deep tones of indigo and brown predominating, while the bright hues and tints only appear to point out and heighten the effect of the pattern. Below indigo, marrone or brown, the deepest shades used in this manufacture should never go, and the highest tints are recommended to be mellowed down with some warm colour. White, when introduced, should in like manner be toned down by a gradation of the lightest tints, so as to avoid the appearance of being spotty and broken. When employed as the groundwork, white should be reduced in intensity, and where red and yellow prevail, it should be raised to a cream colour. When, however, the tone is cool, blue or green being the prevailing colour, the authority which we have already so frequently quoted, recommends that the white should be tinged of a gray or purple, or any other cool tint or shade. Of course when white is used as a contrasting colour and not as a medium, it should be tinged of a warm hue. Orange, when used in a carpet as the key colour, requires that the blue should be subdued either in quantity or intensity, and neutralized by the introduction of a small portion of orange. When orange is so used, russet, citron, and brown should be employed as the medial hues, occasionally relieved by the deepest tones of indigo. Here black and white are particularly out

of place. Russet is particularly useful in all arrangements which are adapted for carpet patterns, and so is indigo from its strong contrast to bright yellow, while it dyes well, being clear and free from sootiness. Mr. Hay points out, as a particular error in the designing of carpets the introduction of deep and pale colours, which may have been well chosen with regard to their hues, but not as to their particular degrees of strength or tint. Thus a pale tint of blue is often introduced as an equivalent to the brightest orange, and sometimes a small portion of lilac or pink as a balancing colour to a quantity of the most intense yellow.

What has been said as to hangings, &c., bears upon the subject of wood furniture, for covers and seats must be made to accord with the wood. In contrast, green stuffs must be used with red woods, as mahogany, &c., and purple or blue with yellow woods; in melodizing the woods a contrary course must be pursued. In this kind of arrangement particular care must be taken that the tones are brought to a corresponding degree of intensity, for which much skill is required. With regard to mahogany, with which the decorator has so frequently to deal, it may be regarded as a russet or red, and we have already cautioned him not to use bright red colours with it, as crimson, &c., nor orange or purple reds, as scarlet, &c., for the brightness of these colours subdues the colour of the wood, and makes it look no better than oak or walnut. Oak may be considered as a citron.

With regard to pictures, I have, when speaking of picture galleries, sufficiently shown what grounds to use with them; as to frames, something further may be said. Gilt frames are preferred with large oil paintings, and also with dark engravings, and lithographed portraits when a sufficient white space is left around them. Bronze frames do well with oils representing scenes lighted by artificial light. By using coloured frames, pictures are very much modified in appearance. Black weakens the shades, and bright tints suffer more than half tints, while for lithographs the red of the ink is rather raised than lowered. Gray does not weaken the bright tints and half tints, but then it does not raise them so much as white, while it gives them a reddish cast. Gray has the singular property of giving a perspective harmony which is possessed neither by black nor white, and orange has an effect directly opposite. Red reduces the red tones and gives a greenish hue. Green weakens browns, but heightens other tones, and is agreeable on the whole. Blue has the strongest effect with lithographs, giving them a bistre or sepia colour.

For bronzes those of a dark green colour require a red ground, and when light coloured and new, a bluish ground.

REMARKS ON SHIPS OF WOOD AND IRON.

REMARKS on the relative advantages of the employment of wood and iron in the construction of ships have appeared at different times, in Journals devoted to inquiries relating to subjects of this nature, but a spirit of partizanship has been commonly displayed by the respective advocates of wood and iron in favour of their own views. In an endeavour to avoid this charge, it will be expedient to advert in the first instance, to the different modes in which wood can be employed in ship building, especially as the advocates of iron are in the habit of referring to the defects of ships built of timber, which are capable of being obviated by a different system of construction.

The relative merits of wood and iron for this purpose will, I apprehend, come more fairly before the public by an exposition of some of the plans that may be adopted in the construction of ships of wood; and it appears to me that three well marked systems may be distinguished. 1st. The common plan of timbers, whether framed or single, separated by spaces from each other, whose principal connection with each other, arises from an external and internal series of planking. 2nd. The plan used in her Majesty's dock yards, of timbers wedged up solid, and covered by an external planking, (timbers placed close together I conceive would be found to be a better method.) 3rd. A plan of constructing vessels of any size by two or more connected series of

planks without timbers; this method has not been extensively used. Clunker-built boats belong to this third system, and perhaps also iron vessels, inasmuch as the plates of iron of which they are formed are of far more importance than the iron ribs, which occupy the position of timbers.

The advocates of iron have, I apprehend, by no means exaggerated the defects of ships of the common construction, in which the connexion of the timbers with each other is extremely imperfect, even in the best built merchant ships, and the safety of the largest vessels is dependent on the security of the fastenings of the butts of a 4-inch plank.

I consider these defects are so fatal that no increase of strength or improvement in workmanship can more than palliate them in a greater or less degree, and I propose to abandon any reference to these vessels, and at once admit their inferiority to vessels constructed of iron, provided the latter are made of sufficient strength.

A large proportion however of the present enormous annual loss of merchant ships seems to have been sufficiently traced to defective methods of construction, and to the facility it affords in covering the defects of cheap ships; still the causes that tend to foster the continuance of the present system are subjects foreign to the tenor of these remarks; the fact that the rottenness of the timbers can be concealed from casual inspection, is sufficient for our purposes. It has been urged that unless spaces are provided between the timbers, for the accommodation of water from leaks, that it would rise in the vessel and spoil the cargo. This argument is founded on the assumed necessity of leaks, but it affords proof of their frequent occurrence in vessels of the usual construction.

The rapid destruction of timber by the united operations of wet, heat and filth, and the generation of foul air from these causes will not be denied; and in addition to its weakness the rapid deterioration of the frame of the vessel, from the above causes, seems an equally fatal objection.—though exceptions may occur owing either to care or accidental conditions.

The second system of ship building with timbers wedged up solid, has been in use for a considerable period for ships of war, and the success that has attended this plan has been amply proved by the accounts of the escape of different vessels, that have since its adoption been driven ashore and got off again, in many instances without injury, and in other cases damaged to such an extent as would have insured the total loss of vessels of the common construction; for instance, the *Pique* lost a large portion of her keel, and in some places the whole of the garboard strake, and a part of the floor timbers were ground away by the rocks of Newfoundland, and yet this frigate crossed the Atlantic without a rudder, under circumstances, it must be admitted, of some anxiety to the officers and crew.

For merchant ships I should propose to use the same weight of materials as are now employed, the outside planking would remain without alteration, but the quantity of wood in the ceiling would be added to the width of the timbers, and in case it was insufficient to fill up the spaces between the timbers, the depth of the latter must be lessened to make up the deficiency.

Under these circumstances the timbers would be about double the thickness of the outside planks, and being placed close together, a good means of connexion might be obtained by large dowells or coaks, so as to produce a mutual dependance on each other, and so that any pressure on the outside would exert a more regular strain on every part. A vessel constructed on this principle would be an irregular cask, and when caulked inside and outside would float without planking; and by the addition of the latter, a frame of great stiffness, and equal strength and thickness in every part would be obtained, on which one side of every piece of wood used in its construction would be visible, and would allow an examination to be made of its state with great facility. The other sides of the wood would be preserved from wet as long as the fabric of the vessel remained sound, and the caulking was attended to. It is obvious that a greater inside width of 7 or 8 inches would be gained in these vessels, and no loss of space would accrue if it was occupied by battens to admit of water accommodation for the leakage,

and the prevention of injury to the cargo from the escape, until at least the present advocates of the assumed necessity of leaks in ships, became convinced of the small prospect of their occurrence under common circumstances in vessels so constructed.

It is true no provision will afford security to vessels on rocks among breakers, but such situations afford the best test of the merits of different systems of ship building, by the time each vessel is found capable of resisting these effects.

Numerous cases will occur where life is dependent on the time the vessel holds together, but the partial saving of the cargo may be considered objectionable by ship owners, among whom the advantages of a total loss are well understood. Opinions on these points are of little value, we must wait for evidence from wrecks under different conditions.

The scantling proposed for merchant ships would, I apprehend, be not quite so heavy as that in use for ships of war of equal size; at the same time, it is probable that the strength of timbers placed close together, except that of the dockyard plan of timbers wedged up, to such an extent that a greater strength may be perhaps obtained at a smaller cost. Plans of this nature are obviously only suited for good workmanship and good materials; but it ought to suit, for less insurance premiums, whenever an inquiry on this subject is properly conducted, and explanations are afforded to insurers of such a nature, as shall be fully understood.

The third plan referred to, requires similar conditions of timber and workmanship, but it has not been extensively adopted. Ten or twelve series of inch planks were employed many years ago, in a 500 ton vessel built at Rochester, but I conceive three or four series of 2½ to four inch plank, according to the size of the vessel, would be found a more convenient method of construction.

Several of the Gravesend steamers of 150 feet in length have been built of three series of 1½ inch planks, and they have run for 4 or 5 years, and are now said to be as sound as when first constructed, such at least was the case with the *Ruby*, when opened for the purpose of lengthening the bow to increase her speed.

This method however requires farther trial, especially at sea, before any decisive opinion can be given on its comparative merit; it is favourable to soundness, as the necessity of sawing the wood into planks admits of the certain selection of good materials, and would afford great facility in seasoning timber properly. While the expense of selection would in some degree be lessened by the conversion of the rejected planks to inferior purposes, or by working it up in inferior or cheap craft, perhaps for river use. The increase of cost would not answer unless it was accompanied by a proportional increase of durability, and perhaps the general opinion would be in favour of the latter result, as a necessary consequence of the selection of good timber.

The launches used in the navy have for several years been made on Johns' plan, of two series of planks crossed diagonally, their weight is about ½ of the boats of the old construction, and their durability has been much increased. The Gravesend steamers are built with two similar series of crossed planks in lieu of timbers, covered with an outside planking in the common mode, the whole well fastened with copper.—in large vessels perhaps a ceiling connected in the same manner might be deemed advisable: at the same time it seems probable that a greater strength would be obtained by a less quantity of timber in the third than in the second method of construction proposed. Clunker built which belong to this class, in which the principal strength depends on the planking instead of the timbers, seldom exceed 100 tons in size, and are usually of a slight scantling; their great durability is well ascertained, provided they are kept from the ground, in which case from the thinness of the single part of the planking, holes are easily knocked in their bottoms.

The introduction of these methods of constructing timber ships is not likely to be effected, except by the nearly total destruction of the present trade in ship building, by the more general adoption of iron vessels, and the interests of humanity will cause the earliest occurrence of this result not to be regretted. Nothing perhaps but the

severe pressure of iron competition will induce the present race of ship builders to turn their attention to the means whereby greater strength, security and durability may be given to wooden ships; eventually perhaps its greater strength for a given weight, and its greater elasticity may obtain a preference.

Prime cost undoubtedly will form a principal element in the approaching competition; at present iron vessels are often built too cheap, or in other words too slight; the error may be, and I believe has been remedied. Innumerable questions will arise relating to the elasticity, strength and durability of wood, as well as its quality; and also in reference to the destructive action of salt water on iron, the strain on the rivets, &c. &c., which can only be answered by experience.

To a spirited competition between wood and iron I look for the improvement of vessels of both materials. Recently I have met with parties who being engaged simply as owners on the proposed construction of a steam boat, in consequence of the difficulty in the choice of wood or iron, have found it necessary to institute an inquiry respecting their relative merits in ship building; these parties, but for the difficulty of selection, would have gone on in the good old jog-trot way of supposing, that British ships of the old construction were perfect specimens of the art, and would have patiently submitted to the present rates of insurance, as founded on the average loss, deduced from defective ships. The spirit of inquiry once roused among owners of shipping, will I trust lead to results as yet scarcely anticipated.

It matters little to the country whether wood or iron eventually obtains the preference; if British oak is abandoned it will be only superseded by British iron, and the inhabitants of our land ought to be satisfied if the latter will uphold the character of the navy as well as the former has done.

At present I consider the question of relative superiority as undecided, and though disposed to admit the inferiority of timber vessels of the common construction, yet the advantages of iron may not exceed that due either to the methods of construction adopted in the navy, or in the Gravesend steam boats. The latter method is perhaps best adapted for small, and the former for large vessels. Moreover, we want the evidence likely to be afforded by the wreck of the largest iron steamers, for the formation of an opinion respecting their powers of endurance under the breakers of a rocky shore, or a sand bank.

In regard to the relative advantages of the two plans of ship building proposed for the merchant service, the method adopted in the navy has received the stamp of experience, and the evidence is conclusive in its favour. The 500 ton vessel built of planks before alluded to, was driven on shore in a heavy gale under Mount Batten, in Plymouth Sound, when loaded with Ordnance stores, in company with 10 or 11 other vessels, all of which became total wrecks; she afforded an almost solitary instance of a vessel saved, when ashore on that point, and she is reported to have rebounded from the rocks for a short time like a cask, until a hole was knocked in her bottom; after the gale she was got off, and was repaired at a moderate expense, and proceeded on her voyage to the East Indies.

I should also be inclined to the opinion that a greater strength will be obtained with a less quantity of materials, by means of several series of planks than by close timbers and outside planking, but the latter plan seems to afford greater facility for repairs. In conclusion, I would remark that it is my object to assert the possibility of the introduction of great improvements in the construction of vessels of wood, without any increase, and perhaps at some reduction of cost, and I wish to induce parties engaged in ship building to advert to the fact, that the best portion of their business, the construction of steamers is rapidly passing out of their hands, and that unless sailing vessels are rendered stronger, safer, and perhaps lighter, this portion of their trade may follow, as the establishments for building iron vessels are increased, or at least such a depreciation of prices may occur as will be equally ruinous to them.

At the same time I must acknowledge that great improvements in regard to strength have been necessary, and have been adopted in many of the larger steamers, in some instances perhaps to the full ex-

tent here advocated, at least in the engine room; similar principles might be adopted in the fore and after bodies with lighter timbers, and hence a less strain would be thrown on the midship body in passing over heavy seas. It is their general adoption that I would urge, and I cannot but express my conviction that steam ships of the largest class yet made, may be constructed to bear the winter seas of the Atlantic, by a better disposition of the timber employed in their construction.

Y.

HAS ATLANTIC STEAM NAVIGATION BEEN SUCCESSFUL?

ALTHOUGH practical men are usually ready to acquiesce in those deductions of the philosopher which relate to the establishment of abstract principles, they are too apt to resist any attempt to apply those principles to the analysis of the transactions of real life. General truths are usually treated as if they were individual fallacies: and a hypothesis however just, requires to continue inert in order that it may remain uncensured. All men look upon general rules as being applicable to all cases except those in which their own antipathies or predilections happen to be enlisted, and however clear men's judgments may be upon indifferent topics, they appear incapable of apprehending the force of the plainest argument if establishing a conclusion adverse to their supposed interests. Hence the imperfect success of attempts, to fix the current value of political or commercial measures by the aid of philosophical research. Some powerful vested interest is sure to step in to prove, "by most sufficient reasons," that the subject under inquiry is exempt from ordinary jurisdictions—that its peculiar features constitute it a case *sui generis* which the said vested interest is by far the best qualified to illustrate. Truly the public has much to be thankful for, from an intervention so discriminating and disinterested!

But the philosophers are sometimes censurable also. There is a philosophical as well as a popular infatuation, the former consisting in unwarrantable generalization, as the latter in irrational speciality. Things alike are yet things different, and although in the generic distribution of a subject it is impossible to take cognizance of minute differences, yet those differences must by no means be disregarded when an individual case is singled out for examination. Philosophers are too apt to pay exclusive regard to leading characteristics—to overlook those limitations and peculiarities which distinguish everything in nature from that which it most nearly resembles, and without an attention to which, general rules cannot be rendered strictly applicable to the diversified cases which arise in practice.

The obvious remedy for these evils is for the practical man and the philosopher each to abate somewhat of his characteristic prejudice. Let the practical man trust a little more to reason, and the philosopher a little more to experience, and let the practical man take the proper steps to cure himself of that mono-mania which the intermingling of considerations of private interest with philosophical investigation usually generates. He should adopt the synthetic rather than the analytic method of investigation, and should be more intent upon tracing resemblances than upon multiplying distinctions. He should reason from principles to examples rather than from examples to principles, and should rather regard principles as the exponent of results than attempt to raise results into an antagonism of principles. The philosopher should carefully examine whether the case he has undertaken to investigate be not an exception to a general law—or whether it may not possess such distinctive qualities as may materially modify the final result. He should ascertain the precise point at which the case under review diverges from other cases the most nearly coincident, and should assure himself that he has overlooked no circumstance capable of influencing his conclusions. It is only by an observance of these rules that either practical or scientific men may hope to obtain results undistorted by prepossession, prejudice or passion, and we

should hope to witness the adoption of these means of arriving at a correct conclusion in the investigation of the merits of Atlantic steam voyaging, were it not an invariable attribute of keen disputations that the attainment of a correct conclusion is regarded as matter altogether unimportant.

The clamour and confusion which marked the original discussions relative to Atlantic steam voyaging have now happily subsided, but although they made such an unceremonious noise, they have left no very distinct recollection as to what that noise was all about. In truth it was not very easy to tell that, even at the time: for so much of palpable absurdity was mixed up in the doctrines currently attributed to the most distinguished of the disputants, as to destroy in the minds of men unaffected with the steam *rabies*—all confidence in the genuineness of the imputed declarations. Men of penetration indeed regarded the representation that suppositions pregnant with absurdity were the sentiments avowed by eminent inquirers, as a sort of *ruse de guerre* intended to shake the reputation of those whose arguments were unsuceptible of refutation. But the manœuvre was successful—the advocates of the Atlantic enterprise were “willing to swear any thing for their client,” and the faith of the multitude was equally comprehensive. Many of the absurdities so industriously disseminated as the sentiments of distinguished men, were really in some measure believed to be the veritable doctrines of those eminent persons, and of those who rejected such a supposition, but a small proportion was aware of what the actual doctrines really were. We have been at some pains to supply this defect of information from authentic sources: it is our present purpose to state,—1st. The nature of the opinions really entertained upon the subject of Atlantic steam transit antecedently to its establishment; and, 2ndly, The present condition of the Atlantic enterprise, restricting the meaning of that term to the line of communication between Great Britain and New York, to which it was originally applied.

The discussion of the question of Atlantic steam transit first attracted the public attention during the meeting of the British Association, held at Bristol in 1836. One party alleged that the establishment of a line of steamers between Great Britain and New York, of sufficient size and power to enable them to perform the passage IN ONE TRIP, would inevitably be a most beneficial speculation. Another party, of which Dr. Lardner was the representative, contended that there were no good grounds for believing that the performance of the voyage IN ONE TRIP was practicable, with sufficient economy to render the enterprise successful; but that if the voyage were resolved into suitable stages, the enterprise might then be brought under conditions which promised a fair prospect of a beneficial result. To understand clearly the force of the reasonings, we must first have a clear conception of the capabilities of steam navigation.

If any given steam vessel, moved according to the ordinary practice, by the conjoined agency of steam and sails, be laden with coals to the extent of her capacity, she will in that state be capable of performing a voyage of a certain determinate length, with her engines acting for the whole time at their full power. Now it is well known that the same vessel is capable of making the same voyage by the agency of sails alone, for although steam vessels when propelled by sails alone, without working their engines, may be inferior in speed, or in nautical qualities, to an ordinary ship, yet we know that they are capable of performing long voyages unassisted by steam, as has been abundantly proved by the voyages of the Madagascar and other steam vessels to India, as well as by numerous government and other vessels. Between the performance of this voyage with the greatest expenditure of fuel, which will in ordinary circumstances be when the engines are worked at their full power, and with the expenditure of no fuel at all, we may manifestly fix upon a given point where the expenditure of fuel during the voyage shall be precisely what we please. For we may either work the engines during the voyage for such a proportion of the time as shall exactly consume the quantity of fuel we have fixed upon, or we may work the engines for the whole period of the voyage, with such a diminished exertion of power as is capable of being produced by the quantity of fuel we propose to consume. We may there-

fore easily maintain the machinery of a steam vessel in uninterrupted action for any length of voyage we think proper, provided only that the amount of power exerted by the engines be correspondingly diminished, or what is the same thing, that the engines be, if worked at their full power, correspondingly small. The question therefore of the practicability of a steam voyage of any length whatever, resolves itself into the practicability of making ships very big, and engines very little; a question which can hardly be supposed any one should be so insane as to contest. Yet even this absurdity has been attributed to Dr. Lardner, who is represented to have said at the Bristol or Liverpool meeting of the British Association, that for a steamer to reach America was a physical impossibility; and this too in the face of the well known FACT that the steamers Savannah, Curaçoa, &c., had already crossed the Atlantic long antecedent to the date of the Bristol meeting! And was a falsehood so preposterous believed? It was—and is probably extensively believed to the present day. But it will be objected, “Dr. Lardner said that we might as well attempt to establish a steam communication with the moon as with America.” If Dr. Lardner ever made use of any such expression, we presume he only meant to intimate that the Atlantic enterprise was in his opinion a visionary one. When we talk of a bubble speculation, we do not in general mean that the said speculation has reference to the manufacture of hollow aqueous spherules—or if we speak of sunset or sunrise, we are not usually interpreted as expressing our disbelief of the Copernican system—so in like manner if we institute an analogy between any given enterprise and a tunnel through the earth, or a railway to the moon, we are usually understood to express our belief that it is of a very hopeless character. Of physical impossibilities we rarely venture to speak—the subject is abstruse. We should not be warranted in saying that *in rerum natura* it was a physical impossibility to bore through the earth, or with the assistance of photography to have a telegraphic communication with the moon, yet we are warranted in treating projects such as these as “trifles light as air,” and in associating by a common figure of speech, projects of which we would express our disapprobation with these unsubstantial fantasies. It is difficult to discover upon what principle Dr. Lardner is to be deprived of the use of the universally employed language of metaphor, or why a doctrine is to be forced upon him which every man in his senses must utterly disavow. But it appears obvious to us that no very figurative acceptance of the expression attributed to Dr. Lardner is necessary, as will appear plain enough from the following considerations.

The mere abstract practicability of performing voyages of any length whatever by steam vessels is so palpable that it cannot require another remark. But in practice other considerations arise. The vessels must be of a sufficient power to ensure a rate of progress considerably superior to that of sailing vessels, and they must be so capacious that whilst furnishing sufficient stowage room for coals, they will render comfortable accommodation to passengers, and space for a moderate quantity of cargo. These questions being satisfactorily disposed of, another question of still greater consequence presents itself. Will vessels of the size indispensable for long steam voyages, of adequate power, capacity and accommodation for the navigation of the track of ocean between Great Britain and New York in one unbroken voyage, PAY THE PROPRIETORS? The question of success or failure is sooner or later merged into the question of profit and loss.

The profit or loss of steam voyaging is manifestly a function of a multitude of local and individual circumstances, which are incapable of reduction to any general form of expression. But *ceteris paribus*, the longer the voyage is without relays of fuel the more remote becomes the prospect of a successful result. For in proportion as the length of the voyage is increased, the size of the vessels suitable for the performance of that voyage must be increased in a corresponding, though not in the same ratio, and the expense of maintaining steam vessels of such power and tonnage as to be adapted to the performance of unusually long voyages, is such that scarcely any line of independent unprotected traffic is sufficient to sustain it. It may hence be safely assumed as a general principle that in cases where the only sources of revenue are the profits upon freights and passengers, and the pecu-

liabilities of the voyage at the same time demand the employment of steam vessels of similar size and power to those constructed for Atlantic voyaging, the success of the enterprise, that is, the continuance of a profitable and satisfactory issue, will be, to say the least of it, as is proper in a case judged *à priori*, exceedingly problematical.

The limitation which exists to ocean steam voyaging is *expense*, not *impracticability*. This limitation is in the present state of the art immovable and insuperable, and the establishment of a steam communication with the moon, is quite as feasible as the profitable extension of steam voyaging in the present state of the art, to cases to which it cannot be profitably extended. The attempt to surmount difficulties by shutting our eyes to them, is not merely futile, but is in this case productive of unmerited disfavour towards steam navigation. For the origination of enterprises, which from their nature cannot be capable of yielding an adequate profit to render them permanent, destroys public confidence, and fearfully represses the spirit of commercial adventure. There is no achievement which ought to be more grateful to the public acceptance than the analysis and exposition of such illusive enterprises, yet there is none which frequently obtains a more ungrateful requital. Persecution and calumination appear to be the heritage of the public benefactor, and the same dark spirit which administered the poisoned cup to Socrates and Phocion, is not extinct at the present day. Yet it is the part of philosophy to bear contumely without depression—nor ought the sensibilities of the philanthropist be frozen by the breath of popular aspersion. If it be beneficent to attempt the dissipation of popular delusion, to continue that attempt unmoved by calumny, violence and derision, is surely an approach to divinity. We trust that Dr. Lardner may long continue his patriotic endeavours to direct aright the national energies in any questions similar to that which forms the subject of the present enquiry. Those energies if suffered to run to waste will produce a vegetation which may be fair for a season, but which will inevitably prove itself to be deadly and delusive. Like waters poured out in the desert, they may cherish flowers pleasing to the eye, but bearing death in their exhalations—trees of luxuriant foliage and majestic stature, but hollow and poisonous within; fruit of tempting appearance, but turning in the grasp into bitterness and ashes. With the view of assisting our readers to form a correct estimate of the true character of the Atlantic enterprise, we shall recapitulate some of the circumstances attending the discussion of that question. The asperity which characterized the discussion at Bristol, as well as the subsequent discussions at Liverpool and Newcastle was a prominent feature of the inquiry, the more so that it happily rarely attaches to statistical and philosophical investigation. The cause of this unbecoming heat has been attributed to the fact of considerable interests having been already enlisted, antecedently to those discussions, in the schemes which Dr. Lardner found himself constrained to condemn. The managers and directors of these several embryo projects were, it is said, in conformity with our opening exposition of the besetting frailty of practical men, incensed at the application of Dr. Lardner's general conclusions respecting steam voyaging to this particular case, which they contended ought to be and was an exception. It was considered that the clearness of Dr. Lardner's expositions established a conclusion opposed to their interests, and involved an indirect reflection upon their capacity or disinterestedness, whilst engineers and other artificers were not without that bias in favour of the Atlantic enterprise which the anticipated fabrication of immense vessels might be expected to create. Though unable to cope with Dr. Lardner in argument, this united party reasonably concluded that Dr. Lardner was entirely wrong, because they were undoubtedly entirely right. They therefore attempted, and not without some temporary success, to undermine his reputation for practical sagacity, by attributing to him sentiments he never entertained, and then showing those sentiments to be altogether fallacious. When the phantoms thus arrayed, as if they had been real entities, had been valiantly slain, the victory was manifestly won, and was so adjudged by "a discriminating and enlightened public." That the popular voice should have adjudged to the advocates of the Atlantic scheme the superiority in the discussion of that question is a circumstance which

has been supposed to be partly due to the effect which *any* doctrine is capable of creating in the public mind if incessantly insisted on, but chiefly to the contemporaneous development of the most extravagant popular anticipations relative to steam agencies. This species of delusion has been not inappropriately termed the Steam Mania. During the severity of its paroxysms, projects the most preposterous were received with eagerness and applause, the country was drunk with expectation, and for a time appeared bereft of every atom of its accustomed discretion. In so distempered a state of the public mind the project of Atlantic steam voyaging could scarcely fail to attract numerous admirers. The magnitude and grandeur of the enterprise captivated the popular sympathies, whilst the implicit faith in the omnipotence of steam agencies smoothed down all difficulties and surmounted all opposition. But although enthusiasm may win a battle, it is only the material interest of mankind which can keep the field. Reason may be overborne for a season, but is sure sooner or later to obtain the superiority. A few years of experience generally brings with them the subsidence of the most inveterate popular delusions. Men awake as if from a dream, and it is an honourable trait in the character of public opinion that it has no resentments to perpetuate, but is desirous to atone for whatever injury its frenzy may have inflicted.

A very clever writer in the Quarterly Review, No. 123, (1838) undertakes to point out the magnificent prospects of Atlantic steam voyaging, and the advantages direct and consequential which may be fairly expected from it. The period at which this article was written, shortly posterior to the accomplishment of the first voyages of the Great Western, was peculiarly favourable for lending weight to the reviewer's conclusions, and the writer is evidently a man of much general ability.

We shall proceed to make extracts from this article, as an example of the arguments adduced in support of the advantage of the Atlantic scheme.

"The effect of this achievement is by no means easily to be described or foreseen. Even the Americans with all their reputation as a self possessed and considering people, have displayed unwonted raptures and antics on occasion of the first arrival of the Sirius and Great Western at New York, quite as much so as our Bristol neighbours on their return, and we are not sure that either party is to be blamed for it. We are not sure that the former are far out of their reckoning when they speak of this as a new epoch in the history of the world. We can enter into the feelings of the myriads who crowded the wharfs at New York, when the English boats were hourly expected, when finally after days of almost breathless watching (which to fearful spirits might well have afforded some pretext for disbelieving the new scheme, some excuse for casting even ridicule on it after all), at length on the morning of St. George's day, the doubts, the fears, the scorn were alike destined to be removed for ever from the mind of every living creature, (even, we dare say, but let us say it with due deference, from that of Dr. Lardner himself), for now appears a long dim train of distant smoke in a somewhat unaccustomed direction, it rises and lowers like a genius in the Arabian nights portending something prodigious; by and bye the black prow of a huge steam boat dashes round the point of some green island in the beautiful harbour

Against the wind, against the tide,
Steadying with upright keel."

It is not very easy to perceive what these doubts and fears really are which the first voyage of the Sirius was destined to remove for ever. The doubts and fears of the possibility of a steamer being able to cross the Atlantic? Dr. Lardner can hardly be conceived to have entertained these doubts and fear, for one small reason among many others, the passage across the Atlantic had been accomplished by a steam vessel about twenty years before. Are the doubts and fears meant to have exclusive reference to the profitable issue of the undertaking? How could the success of any enterprise in steam navigation be ascertained by the performance of a single trip?

"The British and American Steam Company who have just launched at Blackwall a ship thirty-eight feet longer than any in her Majesty's

may, notify to us moreover that next year they mean to have boats like this running on each side on the 1st and 16th of every month. This is but one company, one which has not yet moved we believe, for we understand the Sirius to have been sent out by another, and the Great Western it is well known belongs to Bristol. Glasgow too will no doubt bestir herself, and above all we must leave room for Liverpool. The sole marvel is that Liverpool has waited so long, a secret only to be explained by the extent of interest there invested in the American liners. We see that a company is now started at that port who announce immediate operations."

To us it appears still more marvellous that the establishment of Atlantic steam voyaging should have been accomplished by England at all when America had palpably the greatest benefit to receive from the execution of that measure. The Americans would it is alleged have taken a share in the Atlantic enterprises had they not built their hopes upon a project which was to send a ship across the Atlantic by the instigation of a barrel of blue vitrol, but which failed. This circumstance is however insufficient to account for the torpidity of the Americans, where there is anything expected to be won. Had the expectation of a profitable result been as sanguine in the United States as for some time it was in England, it is the opinion of the best informed persons that we should not have been left to enjoy the steam monopoly of the Atlantic. The fact appears to be that the Americans were better judges than we were of the amount of profit to be realized by the transport of passengers and light articles of merchandise across the Atlantic, arising in part from the experience they had had of Atlantic steam voyaging before we began. "Scarce ten years had elapsed after Fulton first committed his novel little pinnace to the waters of the Hudson, ere the Savannah, a new steam vessel of 300 tons crossed from New York to Liverpool, and at several subsequent periods has the voyage been accomplished. The reason why Atlantic steam voyaging has not grown up among the Americans may be traced to the conviction that the adventure would not be productive of that Honey of Hyblas, vulgarly called MONEY."*

The Quarterly proceeds—"What is to prevent a fair competition now? What account is to be made of a curve or two in a river with steamers of 300 feet long, and a speed of 15 miles an hour, as practical men best versed in these matters expect to see in a very few years? And indeed the American boats upon the Hudson have been running at much more than this rate for years." We confess we should like some verification of all this before we believe it. Our readers may try their penetration upon the following, which to us appears mere childishness.

"We were speaking, however, of the first sensation, the achievement has produced, and which we venture to predict will at some future day be a matter of no little historical curiosity. The New York editors seem scarcely able to contain themselves, 'side by side with the old world at last,' says one, 'Now then for the coronation,' cry half a dozen more—and then the files of European journals unrolled! Fifteen days from Bristol, &c. &c. A revolution this such as the world rarely sees even in our eventful age—a revolution thoroughly overturning the old systems of most of the business world at least—yet effected as it were instantaneously, and without one drop of blood."

The following is a magnificent example of that figure of speech usually termed nonsense.

"Some one has predicted that presently we shall have Covent Garden market stocked by the other continent; as to the floral department there may be something in it for aught we know, and indeed in some others too, for if the 'liners' could bring the Duke a present of fresh venison from his western admirers, we certainly get a clear vision here of divers good things to come. We say nothing however even of Yankee ice dropped in dog days at sun-rise upon every door step in London as in Boston—not one word—'Nil admirari,' we repeat, is our motto; 'keep cool,' that is, ice or no ice—dog days and all."

But further. "It is only thirty years since Fulton ascended the Hudson with his boat. In 1810 there was no such thing in all England,

and as late as 1820 there were only thirty-five. The most important improvements also have been very recently introduced, and without particularizing these, it is sufficient to say that the learned Dr. Dionysius Lardner's miscalculations on this subject of Atlantic navigation, have evidently been caused by almost wholly overlooking these same improvements, even so far as some years past are concerned, (and a year in such a progress as this agent is making is a matter not to be overlooked), or regarding them too much as mere speculations not likely, or not yet fully proved to be capable of great practical effects (as they have already been), while as relates to what may yet be established, though now it is but experimental; or of what may be discovered of which nobody now dreams, the calculations in question have apparently left no lee way for the ingenuity or our successors, or even our contemporaries. It was taken for granted that all had been done which could be done—that there were not any 'hidden powers' hereafter to be brought to bear upon steam navigation, as well as upon other things, and to supersede steam itself altogether. How grand a mistake this was we need not say, let us beware of its being made again."

In reference to this statement it is proper to observe that Dr. Lardner's deductions relative to the Atlantic enterprise were formed, as we shall presently have occasion to show more in detail, from the performance of the Medea, and that the Medea was at that time the most perfect existing steam vessel in reference to the distance over which she might be propelled by a given quantity of fuel per horse power.

In regard to the omission of "lee way" in his computation, it is difficult to see upon what grounds the admission of such an element could be justified. Atlantic steam voyaging in the year 1836, either was or was not beneficially accomplishable. The point was evidently alone capable of being determined by a comparison of the difficulties of the enterprise with the existing capabilities of steam voyaging; and how were the existing capabilities of steam navigation to be ascertained except by a reference to the performances of the best existing steam vessels? If Dr. Lardner did this, he did all he was called upon to do; he was not called upon to say that Atlantic steam voyaging would be profitable in 1836, because the progress of improvement might perhaps render it so in ten years time, or in ten months time. It would have been highly unphilosophical to have based computations upon circumstances which were not really existent. No man can say that in any branch of science or art all has been done that can be done, but it is quite time enough to adopt discoveries when they have been actually found out.

Once more—"It cannot be doubted, we think, that the passage of the Atlantic by steam will even in the coming ten years be brought to a state of (so to speak) artistical luxury and perfection, of which those who have started the enterprise themselves little think."

Alas—alas! how has this prediction been verified!

But we cannot enter upon a subject so agonizing as the loss of the President—the wounds are not yet cicatrized, but bleed afresh at the tenderest touch. The wail of the widow and the orphan—of the affianced bride and the childless father, is yet sounding in our ears; and memory rekindles emotions which are only to be assuaged by time the comforter. The repetition of such calamities is now, heaven be praised! unlikely. And oh! what can be the reflections of those, if any such there be, by whom the one dire calamity has been directly or indirectly superinduced? Can any thing be more reprehensible than that reckless precipitation which not merely sets at nought all consideration of failure and ruin, but tampers without compunction with the lives of the best and noblest of the land?

Having in the preceding pages adverted on several occasions to what Dr. Lardner did not say, we shall now attempt to show the nature of the opinions respecting the Atlantic enterprise he really did entertain. We are fortunately in possession of an authentic and well known record upon this subject, in the shape of an article written by Dr. Lardner for the Edinburgh Review, and which will be found in the 131st number (1837), of that publication. From this article we shall make considerable extracts.

* Thoughts on Steam Locomotion. Weale, 1840.

"The imposing mechanical phenomena so rapidly and unexpectedly developed by the invention and improvement of the locomotive steam engine, and its application to railways have for several years so engrossed public attention that other means of facilitating the operations of commerce, and expediting the social intercourse of distant masses of people less fascinating perhaps, but not less important, have been comparatively overlooked. The subject of water transport by steam has from this cause received less than its due share of attention. A re-action however appears to have been recently produced, and we have now a swarm of projectors much more largely supplied with zeal than knowledge, who not content with advancing in the march of improvement with that calm deliberation and salutary caution so necessary to insure a permanently profitable issue for any great undertaking, would rush to their ends without ever informing themselves of the means at their disposal, and proceed *per saltum* from a channel trip to the circumnavigation of the globe.

Within the last year, considerable public attention has been directed to the question of the practicability and advantage of establishing a line of steam communication between Great Britain and the United States, and various projects have been started and companies formed for the construction of vessels for that purpose, several of which are already in a state of forwardness. At a meeting of the British Scientific Association held at Bristol last September, one of the topics which engrossed a large share of interest, was the question of the practicability of a steam voyage across the Atlantic, raised in the mechanical section. The statement laid before that section by Dr. Lardner obtained such publicity at the time through the press, that it would be superfluous to recapitulate its arguments. The conclusions however at which he arrived were briefly these:—That in the present state of the steam engine as applied to nautical purposes he regarded a permanent and profitable communication between Great Britain and New York by steam vessels, making the voyage in one trip, as in a high degree improbable: that since the length of the voyage exceeds the present limits of steam power, it would be desirable to resolve it into the shortest practicable stages; and that therefore the most eligible point of departure would be the most western shores of the British Isles, and the first point of arrival the most eastern available parts of the western continent; and that under such circumstances the length of the trip, though it would come fully up to the present limit of this application of steam power, would not exceed it, and that we might reasonably look for such a degree of improvement in the efficiency of marine engines, as would render such an enterprise permanent and profitable."

Dr. Lardner then goes on to state that it had been objected to his conclusions, that the data from whence they were derived had been obtained from the performance of steam vessels antecedently to 1834, whereas since that period considerable improvement was alleged to have been effected in steam machinery, which by diminishing the consumption of fuel was considered to have improved the prospects of Atlantic steam voyaging. Of all the vessels then existing the *Medea* was universally allowed to be the one which was capable of being impelled over the greatest distance with a given quantity of coals per horse power; she was therefore the most favourable actual standard by which prospects of the Atlantic enterprise could be measured, and was adopted as the basis of the present inquiry. Dr. Lardner then proceeds to show that the same conclusion respecting the Atlantic enterprise which he had already deduced from the performances of vessels antecedently to 1834, was also deducible from the performances of the *Medea*, and of other vessels between 1834 and 1837.

The misconception which has existed respecting Dr. Lardner's opinions upon this question, and which nothing short of misrepresentation prepenance was sufficient to have created, renders it proper here to repeat that the limits which exist to the achievements of steam power are not imposed by any abstract impracticability of performing steam voyages of any length whatever. but by the impracticability of rendering those voyages sufficiently profitable to confer permanency upon enterprises in steam navigation. The doctrine attributed to Dr. Lardner that a steam vessel (or any vessel), if only sea worthy, was incap-

ble of proceeding from Great Britain to the coast of North America, is so palpably absurd that it scarcely deserves to be noticed.

Dr. Lardner has however offered the following observations upon the subject, which we extract from the Monthly Chronicle, Vol. II., 1838.

"A vessel having as her cargo a couple of steam engines and some hundred tons of coal, would be *ceteris paribus* as capable of crossing the Atlantic as a vessel transporting the same weight of any other cargo. A steam vessel it is true would labour under some comparative disadvantage, owing to the obstruction presented by her paddle wheels, and the paddle boxes which cover them: still, however, it would be preposterous to suppose that these impediments would render impracticable her passage to New York. If therefore such a vessel merely transported her machinery and fuel without working the one or consuming the other, she would still make the passage. That a steam ship may be a tolerably good sailing vessel is proved by the fact that the steam frigate *Medea*, one of the most efficient steamers in the service of the Admiralty, accompanied the fleet many thousand miles propelled by sails, and without working her engines at all. If then a steam ship viewed merely as a sailing vessel, freighted with engines and coals, can traverse the Atlantic with certainty, how absurd is it to suppose that the abstract practicability of such a ship making the voyage to New York with the aid of her machinery and fuel can for a moment be doubted!

"In fact no doubt has been entertained or expressed as to the practicability of establishing a communication between these countries and New York, by a line of steam vessels. But a difference of opinion has been entertained as to what mode of accomplishing the object may best ensure certainty, safety, regularity and profit, without which last element it is presumed the other objects could hardly be secured."

Returning from this digression to the Edinburgh Review, we find Dr. Lardner explaining the inconveniences to which extended steam voyages are subject, arising from the incrustation of salt in the boilers, the deposition of soot in the flues, and other matters of that nature, to which we consider it unnecessary more particularly to refer. He then proceeds—

"The several circumstances to which we have adverted, constitute difficulties, having the general tendency to abridge the practicable extent of an uninterrupted steam voyage. There remains a still more serious impediment to the extension of steam navigation inherent in the very substance from which the engine at present derives its mechanical power—an impediment which places a definite and assignable limit, beyond which it is mechanically impossible to extend the voyage of a steamer (of ordinary construction). To form an estimate therefore of the major limit of the extent of a continuous steam voyage, it will be necessary that we should examine, 1st. The proportion in which the capacity of the vessel may be distributed between the machinery, the fuel, and the objects of commercial transport; and 2ndly. The rate at which the fuel will be consumed in propelling the vessel over a given distance, regard being had to her tonnage and power.

"Assuming that a certain extent of the capacity of the vessel is appropriated to the mechanical means of propelling her, that portion will obviously be shared between the machinery and the fuel, by which that machinery is moved.

"The proportion in which this space should be distributed between the machinery and the fuel will vary according to the length of the voyage. As the fuel may be replaced at the end of each trip, and as it is generally advantageous to give the vessel as powerful machinery as the extent of her capacity will admit, it is obviously expedient to reserve as limited a space as possible for the fuel, and to give a proportionably increased extent of room to the machinery. In the shortest class of voyages therefore a smaller supply of fuel being sufficient, a larger space must be appropriated to the machinery, and in proportion as the length of the voyage is increased, the quantity of space necessary for the fuel will be augmented, and that allotted to the machinery diminished. To this there must be an evident limit; inasmuch as the space for the machinery must be sufficiently extensive to contain engines of the power necessary to encounter the difficulties of the navi-

gation, and to insure an average rate of progress greater than that of sailing vessels."

This limit, be it observed, is one of expediency—not of abstract practicability. To state the matter in other words—a certain determinate proportion must be observed between the power and tonnage, else the vessel will be incapable of carrying coals enough for the voyage, or her speed will be so defective as to give her no prominent advantage over sailing vessels. And the adherence to this proportion involves the necessity of employing vessels of such magnitude as to be of too expensive maintenance for the profits of an ordinary trade. For as in a symmetrical vessel the resistance increases nearly as the square of the increment of one dimension, and the capacity nearly as the cube of the increment of the same dimension, so it is in a certain point only in the divergence of those series where a result is obtainable, answerable to the conditions indispensable to Atlantic steamers. And that point is so high up in the series, the resistance and capacity are both so great as to indicate the necessity of employing those leviathan vessels, whose voracious appetite is unappeased by the expenditure of all the proceeds of any merely commercial enterprise.

"To arrive at a practical conclusion as to the major limit of a probable steam voyage under average circumstances of wind and water, it will be obviously necessary that we should obtain some probable approximative estimate of the impulsive virtue of a given quantity of coals of average quality. The consumption of coals, other circumstances being the same, will be proportional to the power of the engine, and it will therefore be sufficient to determine what is the average rate of hourly consumption for each horse power in the machinery."

A table of the performances of a number of different vessels between 1834 and the date of the Bristol meeting, but which we consider it unnecessary to insert here, shows that the locomotive duty of the *Medea* was greater than that of any of the rest; the locomotive duty as defined by Dr. Lardner being "the distance over which a ton of coals per horse power is capable of propelling a vessel."

Dr. Lardner proceeds—"To enable us to establish an analogy between the performances of these vessels and the circumstances under which a steamer would be placed in navigating the Atlantic, it will be necessary to explain some physical phenomena attending that ocean.

"The general atmospheric currents which prevail in directions near and parallel to the equator, from east to west, called the *trade winds*, would have a tendency to produce a derangement in the atmospheric equilibrium, if not redressed by a contrary effect elsewhere. It is known that those remarkable winds are produced by the influence of the solar heat upon the atmospheric belt included between the tropics, combined with the diurnal motion of the earth from west to east. The heated air pressed upwards by its buoyancy, is replaced by currents from either hemisphere, which carrying with them a less diurnal motion than that proper to the tropics, a relative atmospherical motion is produced in a direction contrary to that of the earth's rotation. Hence a nearly permanent wind is produced on each side of the line from east to west. As these currents approach the line, they gradually acquire the motion of the surface, which combined with their mutually counteracting effect, produces those calms which prevail about the line, and which are only interrupted by the hurricanes, whirlwinds and other violent atmospheric commotions which are produced where the contrary tropical currents conflict before their force is sufficiently moderated.

"The stagnant atmosphere thus collected at the line, ascending by the effect of solar heat, returns from the upper regions towards the poles, and coming upon the surface in either hemisphere brings with it the diurnal motion of the equator, which being greater than that of the higher latitudes, prevailing winds are produced from the west. The agency of these causes is manifested in the westerly winds which prevail almost uniformly throughout the Atlantic between the shores of Europe and those of North America. There are other physical causes which mingle their effects with those to which we have just adverted. The extensive regions of North America covered with immense fresh water lakes and primeval forests, supply a current of cold air rushing into the warmer strata over the track of ocean between

the Azores and the American coast. This current from the north-west consequently modifies the re-action of the trades just explained; the result is wind blowing generally in the westerly direction, but varying between north-west and south-west, and sweeping across the face of the Atlantic throughout nearly the whole year.

"Atmospheric difficulties are not the only ones which the navigator has to encounter who crosses this extensive tract of water. The well known Gulf stream is a great ocean current issuing from the channel which separates Florida from the Bahama banks, taking first a direction a little to the east of north, and becoming more and more westerly, until it approaches within a short distance of the tail of the great bank of Newfoundland, where it sets in due east towards the Azores. The width of this current at first one degree, gradually increases until it exceeds two degrees. Independently of the difficulty presented by the stream itself, the zone of the ocean marked out by it is characterised by weather so extremely unfavourable to navigation, that it is cautiously avoided by all outward bound vessels. They invariably either take a course so far north as to be clear of its influence until they approach the western shores, where by taking a southerly direction they convert the westerly winds into favourable gales; or on the other hand proceed first southward till they get beyond the lower limits of the Gulf stream, and taking advantage of the trades, make the western coast. This latter, however, is a route never adopted by the best class of New York packets, except they are reduced to a disabled state.

"The westerly winds which we have described as prevalent across the Atlantic, are accompanied by a heavy sea, which is subject to scarcely any subsidence or intermission. In land locked seas such as the Mediterranean and the channels which intersect contiguous islands, the effect of the wind in raising the waters is rapid and produces a short and chopping sea highly unfavourable to steamers; but these effects speedily subside, and in the Mediterranean especially they produce but a slight influence upon the average rate of vessels, when that average is computed from long continued performances. On the other hand the long swell of the Atlantic is not so unfavourable during its operation, but its effects are incessantly, and considerably more disadvantageous to a steamer will be produced by its continuance, than any which the occasional roughness of the more contracted seas to which we have referred could give rise to."

It is right to observe that a "short chopping sea" is a relative term, having reference not merely to the nature of the waves, but the size of the vessel. That which is a long swell to a row boat is a short unfavourable sea to a small vessel, and that which is a long swell to a small steamer, or even to a steamer of 500 or 600 tons, may be a short chopping sea to one of 2000 tons. The swell of the Atlantic therefore may be of as prejudicial a quality to the large Atlantic steamers as that of the Mediterranean, and of the channels is to the smaller vessels navigating those waters.

Another formidable objection to Atlantic steam voyaging arises from the overwhelming force of the Atlantic storms. The shock of masses of water roused into violent commotion by the accumulated momentum of every wave in the whole three thousand miles of foaming waters is nearly irresistible, and is productive of the most injurious effects to vessels of large dimensions impelled by immense steam power. We ourselves happened to see the *Liverpool* in dock after an exposure to one of these Atlantic storms, and she was really little better than a wreck. The straining she had undergone was inconceivable: the seams of the deck had opened greatly, a great part of the copper had been detached from the bottom of the vessel in consequence of the irregular movement of the planking to which it had been nailed, and the oakum hung out of many of the seams in the exterior of the vessel, even below the water line, from which the great straining had displaced it. The "*British Queen*," it is well known has been similarly injured upon more than one occasion, and the frames of the engines of the *Great Western* have been all broken by the working of the ship. The wear and tear arising from this source is infinitely more to a long large steamer than to a compact well built ship; and the danger resulting from the same cause is not inconsiderable. The

icebergs which are not unfrequent in the latitude of Newfoundland are another source of danger, and the dense fogs met with in the same region are highly unfavourable to steam navigation; whilst the consequences of fire, a by no means uncommon visitation in steam vessels, in the midst of the Atlantic, are appalling to contemplate. Several of these obstacles are manifestly irremovable, and are therefore only capable of being regarded as neutralizing to a certain extent, the benefit, if any, of the scheme. But others, and those the most formidable, are susceptible of diminution by the division of the voyage into suitable stages.

"Seeing then the unfavourable aspect under which the project of establishing an uninterrupted line of steam navigation between Great Britain and New York presents itself, let us consider whether by resolving the voyage into the shortest possible stages, the enterprise may be brought under more promising conditions. For this purpose it is obvious that the most western coast of the British Isles should be taken as a point of final departure. The west coast of Ireland would therefore be naturally selected, fringed as it is by numerous spacious and well sheltered harbours. St. John's, Newfoundland, is the most western port, but this harbour is attended with so many nautical difficulties that it could scarcely be regarded as accessible with that certainty which such a line of communication would require—Newfoundland presents an iron-bound coast; and even Nova Scotia should be avoided were it possible to extend the passage: but the distance from the west coast of Ireland to Halifax comes up to the extreme limit of a (profitably) practicable steam passage. *We greatly fear that any attempt to supersede the necessity of making Halifax a stage must prove abortive.*"

In conclusion, Dr. Lardner observes, "Let us however not be misunderstood. That the passage from Liverpool to New York cannot on any occasion be made in one run by a steam ship, we do not maintain." But he declares his conviction that as a practical, permanent, profitable thing, Atlantic steam voyaging will not and cannot be in the present state of the art successful. And this conclusion he is content to avow, notwithstanding its unpopularity. "In confessing then as we do, that after the most careful and anxious inquiry respecting this interesting question, our fears of the result of such an enterprise greatly preponderate over our hopes, we are sensible of expressing an unpopular opinion. It is the natural and fortunate tendency of the human mind to anticipate success, and we ourselves shared this feeling when we commenced the present investigation, we were wholly unaware to what point results since ascertained would lead us."

We shall offer no further remarks respecting Dr. Lardner's statements, which are well able to speak for themselves, but shall at once proceed to the second part of our subject, viz., the determination of the present condition of the enterprises for maintaining a steam communication between Great Britain and New York. This may perhaps best be shown by an enumeration of the several vessels which have been employed upon that line, and the mode of their respective disposition.

Sirius withdrawn.

Royal William withdrawn.

Great Liverpool	transferred	} Now maintaining steam communication with India, via the Red Sea.
United States (now Oriental) transferred		

British Queen sold.

President lost.

Great Western for sale.

Great Iron steamer, (unfinished)	stopped.	} said to be.

The HALIFAX line which carries out Dr. Lardner's recommendations to a certain extent alone thrives; yet it has been questioned if even it could continue to keep the field without the aid it derives from the conveyance of the mails, unless it were to make the western coast of Ireland, the point of final departure. The question might be worth considering by the proprietors of the Halifax packets as well as by the West India Mail Packet company, whether it would not be greatly to their advantage if all of their vessels were to make the western coast of

Ireland, their point of arrival and departure. But should the managers of those companies think differently, should the shareholders resolve in spite of common sense and Dr. Lardner, to throw thousands upon thousands of pounds sterling into the gulf of DIRECT communication, they are quite welcome for aught we care to continue to indulge so reasonable a predilection.

There is one circumstance connected with the preceding table of the manner in which the vessels are employed in the Atlantic enterprise, which affords an example so striking of the coincidence between the deductions of philosophy and the results of experience, that although it has no immediate reference to the present subject, we cannot permit this opportunity to pass without saying a word respecting it. Dr. Lardner it is well known did not confine his inquiries to Atlantic steam voyaging, he also discussed the merits of steam communication with India, via the Red Sea, and it may be satisfactory collaterally to ascertain what his opinions were respecting that line of intercommunication. We shall find those opinions stated in his letter to Lord Melbourne, published in 1837, from which we extract the following passage: "It has been contended that the question should not be regarded as one to be determined merely upon a calculation of profit, that on the contrary, it is one with which great political and social interests are interwoven so closely that it ought to be adopted even though its entire cost should have to be defrayed by the nation. This principle has been implicitly admitted in the resolutions of the Select Committee of 1834, and it has been explicitly avowed by the late Governor General, by several honourable members of the legislation, and of your lordship's administration. But it is a principle which I think it unnecessary to discuss in the present case, because *there is no proposition, however self evident, which carries to my mind a more clear conviction than I have, that this measure, if efficiently carried into operation, will more than return its own expenses.*" Here is an opinion diametrically opposite to that delivered respecting Atlantic voyaging. Let us inquire how far this conclusion is borne out by experience.

The "Great Liverpool" having in a single season earned a loss to her proprietors of six thousands sterling upon the New York line it was determined to withdraw her; and with another new vessel built for Atlantic voyaging, now the Oriental, to open a communication with India, via the Red Sea. The proprietors of the British Queen, who we have been informed, have sustained a loss of about *sixty thousand pounds* in Atlantic steam transit, became competitors with the Great Liverpool and Oriental for the Alexandrian line, plainly showing that both of those companies after a vast expenditure of money, had arrived at the very conclusion Dr. Lardner held three or four years before. Has it never occurred to the proprietors of those vessels that they might have saved about 100,000*l.*, as well as vast responsibility, anxiety, risk and discredit, if at the commencement of the Atlantic discussions they had prevented their passions from exercising their favourite calling, that of running away with their reason?

A recent meeting of the proprietary of the Peninsular and Oriental Steam Navigation Company enables us to state that oriental steam voyaging has been highly successful, and this result has been attained with the same vessels and by the same management that were incapable of realizing any thing but loss on the New York line. It is plain from this result that the Atlantic enterprise did not fail from mismanagement, even were we not assured, as we are, that Mr. Carleton and mismanagement are altogether incompatible. Can a coincidence such as this between prediction and reality be merely fortuitous?

Has Atlantic steam navigation been successful? Has the establishment of the several lines of steam communication between Great Britain and New York been productive of a permanently profitable issue? We leave the verdict to our readers, our part being merely to furnish such remarks and data as may conduce to the attainment of a just conclusion. Had we set out with a different resolution, we might perhaps have given it as our opinion that the Atlantic scheme had proved itself a signal failure—that Dr. Lardner's views had been confirmed with singular exactness—that

Earth has its bubbles as the water hath,
And this is of them.

But we originally said, as we now repeat, that we do not mean to divulge our own opinion.

One consummation there is devoutly to be wished, namely, that Dr. Lardner will soon return to this country, to resume the wand which, like Prospero, none but its master can wield. We can see no other antidote against that worst of Egyptian plagues, the swarms of vermin with which the track of practical philosophy is now overrun. We are death sick of the reign of minute philosophers. If the choice rested with us, we would say, give us back our wolves again—restore the dominion of barbarism—curse us with any thing except the cant of philosophical imposture—the disgusting egotism of idiotic mountebanks. Dr. Lardner's return to England would be the death warrant of all such quacks, which is of itself a sufficient reason to inspire the ardent desire that his return will not be much longer delayed.

Z.

REMARKS ON THE TRACTIVE POWER OF PADDLE WHEELS.

In the theory of the nautical steam-engine there is no point that deserves more attention than the means employed to obtain propelling reaction from the water. The disadvantages which the various plans at present in use labour under, have been very ably pointed out by the different writers in the appendix to the new edition of Tredgold's treatise, and the mortifying result is that nearly half the effective power of the engine is lost by the motion necessarily given to the water by the paddles and their oblique action. Besides the lost power from these causes, there are other disadvantages which the nautical steam engine labours under. A change in the velocity of the vessel, as well as a change in the immersion of the paddles, alters the relation between the power of the engine and the propelling effect. Under the most favourable circumstances, if the power of the steam generated be reckoned 100, the efficient power acting on the paddle wheel is about 60, and the efficient propelling power only from 35 to 40; the power generated thus requires to be nearly three times the work done. It is evident that under given circumstances with a given engine, a certain relation subsists between the extent of effective paddle surface and diameter of the wheel, to obtain a maximum speed, or in other words a maximum propelling duty. It is probable that the experience of steam ship-builders enables them to fix upon very nearly the best proportions for an average immersion, but is there any method of proving that the best proportions have been exactly obtained. There are not wanting very notorious instances to the contrary. It may be said that exactness in this is not of much importance, as the proportions that answer best in a calm will not do for rough weather, and *vice versa*. Suppose the best proportions have been obtained for calm weather, and an average immersion the same propelling effect will not be maintained if the vessel,

- 1st. Has greater immersion.
- 2nd. Has less immersion.
- 3rd. Is employed towing when not constructed for such work.
- 4th. Has to make way against a foul wind or head sea.
- 5th. Has a fair wind, and employs both steam and canvass.

This arises both from a greater absolute loss of power in application, and likewise from the engine being obliged to work with reduced duty. Since, then, the engine is liable to so many adverse circumstances, it would be a great desideratum if the proportion that exists between the effective duty on the paddle-wheels and their propelling duty could at all times be known. The advantage or disadvantage of any change in the paddles would then be pointed out in a way that could not be misunderstood. The first or effective duty of the paddle-wheels may be considered as proportional to the number of revolutions per minute with the same steam pressure; the propelling duty is measured by the number of revolutions conjoined with the horizontal forward strain of the paddle-shaft on its bearings, or the direct tractive force exerted by the engine on the vessel.

The difficulty is to measure this. Is it practicable to do so by measuring the intensity of the friction of two surfaces submitted to the horizontal pressure? The following has occurred to the writer as one mode of doing this. How far it is practicable or likely to be efficient, he must leave practical men to judge.

The figure is drawn to show simply the mode of action. The beam A presses on B with a varying force. Two wheels C, worked by a pinion P and winch W, are embedded between the beams on one side, and the central friction piece D on the other: the contiguous surfaces being ground perfectly smooth. To the centre friction piece D, an arm K is attached the extremity of which E is connected with a fixture F by the intervention of S, a spring weighing machine or other dynamometer. By turning the winch the wheels C are made to revolve slowly, these, by the friction of their inner surfaces against D tend to draw it along with them with a force which, according to the experiments of Coulomb, Rennie, and others, is nearly proportional to the pressure of A on B, and quite independent of the rate at which the wheels C are made to turn. This force by means of the arm K will be shown by S. To set off the scale upon S, it will be necessary to apply known forces to A. This is the only adjustment required, and may be made on the apparatus before being applied to the engine.

Other arrangements of the apparatus will readily occur. In applying it to four bearings, one winch and spring might be made to answer, so as to give the measure of the tractive power at one observation. As an instrument for measuring pressure, this might perhaps be employed for various other purposes. I fear, however, that it is too simple to have escaped the notice of practical men, and that it has been tried and rejected. If not, the information it is intended to convey has not been thought of such importance as to call attention to any thing of the kind. But while so many conflicting opinions are entertained on the subject of paddle wheels, it appears to be the only thing that will properly bring out the true results of experiments, and distinguish what is due to the build of the ship and what to the paddle-wheels. Those paddle-wheels that evolve the greatest tractive power with the full expenditure of steam are the best for the given immersion, and this would be indicated by the speed of the vessel. But if it were required to find what immersion allowed the engine to exert the maximum propelling duty, the speed of the vessel would obviously not be a proper index, unless the relation between the immersion and tractive power were known. Again, if it were desirable to compare the useful qualities of a paddle-wheel at the same immersion but different velocities, a knowledge of the tractive power is essential, and would be sufficient. This would also be the case in judging of the effects of a rough sea. If we might suppose

steamers generally to have such traction gauges, and a careful register of its indications kept during all weather, and at every variety of immersion, each voyage would have all the character of exact experiments, and the results would bear upon the build of the ship as well as the efficiency of the paddles in the given circumstances. The effects of fair or foul weather would also be made manifest. If the best kept steam logs are examined with the view of obtaining information in regard to the qualities of the paddles, it will be found impossible to make any deductions; there is an absolute darkness merely from there being no way of knowing the tractive power exerted by the engine.

The theory of paddle-wheels has received great attention from several of the writers in the new edition of Tredgold, but it may be questioned if the practical deductions are equivalent to the labour bestowed upon the calculations. Indeed, the circumstances which affect them are too various to be embraced by mathematical formulæ. Besides, the whole depends on a law of resistance which is hypothetical. The masterly disquisition by Mr. Woolhouse seems to exhaust the subject; but the formulæ given by the same gentleman in the foot note at p. 301 will be found the most useful for the purpose of instruction. These, if a little modified and amalgamated with the concluding formulæ at p. 194, would be of great service to the young naval officer. With a little knowledge of algebraic notation, so as to work out the numerical values of each expression, taking numerous examples, he would obtain a facile acquaintance with the peculiar and unique relations that affect the working of the nautical steam-engine. Thus he would become aware of the difference in the proportions that ought to distinguish the paddle-wheels of a towing vessel, the disadvantages that a common steamer labours under when employed in towing, or a towing vessel when steaming by itself, the evils of too deep or too light immersion, &c. A small publication adapted to such views appears to be a desideratum at present, and would be calculated to benefit a numerous class who ought to have a thorough knowledge of the subject. The method of working out numerical examples from the formulæ would be the means of communicating such knowledge without the necessity of mathematical attainments.

It is singular that no notice is taken of the theory of paddle-wheels in the treatises on the nautical steam-engine by Lieut. Otway and Robinson, although in point of importance it deserves nearly as much space as the engine itself. Indeed, it is a subject that deserves the attention of the naval officer more than any other, as a difference in the weather, immersion, &c. so notably affect the amount of work performed by the engine. To be fully acquainted with the power he has at command, he must know, from studying the theory of paddle-wheels, and their connexion with the velocity of the ship and of the engine, how much that power is liable to be diminished or increased by circumstances, that are wholly independent of the condition of the engine itself. A single example will show the importance of this; take that of an 800 tons war steamer which makes 10 knots in a calm, the engines working at full power. The velocity per second is 17 feet; the circumferential velocity of the centre of the paddle boards is 23 ft. leaving 6 feet for the back velocity of the paddle-boards. Now with a head wind and sea sufficient to stop the ship way so that it is just able to maintain its position without drifting to leeward. The greatest power that the engine is capable of exerting, would be reduced to $\frac{1}{3}$ or $\frac{1}{4}$, what it was in a calm. Thus $\frac{2}{3}$ of the steam raised in the boiler becomes useless. The engine becomes paralysed from the connection of the parts being adapted to only one velocity and immersion. If it were possible to construct it otherwise, so that full duty could be maintained in all circumstances, the steamer could make nearly eight knots against such a gale.

To look forward and answer the question—What is required to render the application of the steam engine to navigation perfect? Two great sources of disadvantage present themselves:

1st. The motion given to the water to gain propelling reaction.

2nd. The motion of the piston is not uniform under varying circumstances of immersion and speed of the vessel, neither is the momentum of propulsion communicated by the engine equal in equal times.

With regard to the first it may be remarked, that if the reaction is supposed to take place merely from projectile force given to the water, the quantity put in motion to generate the same propelling force in equal times will be directly as the area of the paddle boards. But the loss from the back action of the paddles will be inversely as the same. If the practical advantage of having small paddle-boards is merely to present less surface to the shocks of a boisterous sea, their surface may be reduced in proportion to the square of the augmented velocity. Thus, taking the previous example, the area of the paddle boards that require 6 feet back velocity, and communicate a propelling duty of 17, may be reduced one half without reducing the duty more than $2\frac{1}{4}$ or to $14\frac{1}{4}$, and the velocity of the ship from 10 to $9\frac{1}{4}$. On the other hand, by doubling the area the propelling duty would only be augmented to $18\frac{1}{2}$, and the velocity to $10\frac{1}{4}$.

The disadvantage of a considerable loss from receding in the water will always exist so long as the propelling reaction is derived from it in a continuous manner.

If the same extent of surface is made to move through the water with double the velocity, it will gain the same propelling reaction from the water in one fourth the time, and to do so will have to move over one half the space; so that if it were possible to apply the power of the engine in this manner, the propelling duty would rise from 17 to 20. But to effect this, it would be necessary to arrange the machinery so as to expend on the water, in a quarter of a second, the power generated by the engine in one second; and on the other hand to distribute the force of reaction derived from the water in a quarter of a second, so as to serve as a propelling power during one second. The action of the oars in rowing is a familiar instance of this; the consequence is a considerable fluctuation in the velocity which on a large scale would be very disagreeable if not otherwise objectionable.

To obviate the second source of disadvantage it would be necessary to arrange the machinery so as to vary the absolute velocity of the paddle floats, according to circumstances, while retaining the same back velocity at all times. To effect this it would be necessary to arrange the machinery so as to vary the absolute velocity of the paddle floats, while, retaining the same back velocity, to obtain this it would be necessary to disconnect the wheel from the engine, and by a shifting leverage to bring the lowermost paddles only under its full action, while the others are allowed to revolve passively by catching the water. It is quite possible to make an arrangement to effect all here that the theory demands, but how far such would be concomitant with practical efficiency, is a much more difficult question.

It may be remarked that the screw propellers are as much influenced by these disadvantages as the common paddles, but they are not so much affected by oblique action or by waves, besides not being so much exposed to cannon shot.

J. W.

Bombay, Sept. 21, 1841.

THE NELSON COLUMN.

SIR—On approaching this column from Whitehall, we become sensible of what appears to be a great mistake in the *position* of it, for while the *statue* of Charles the First seems to rise in the centre of the street, and in a line with the centre of the portico of the National Gallery, the *column* is placed quite to the *left* of that line, so as to appear engaged with the houses near Drummond's Bank, and to rise not in the centre of the street or of the portico, but quite to the left of both, thereby producing a most awkward effect. Upon further examination I found this was owing to the architect having thought it necessary to place it in a line perpendicular to the centre of the plane of the portico, whereas had he erected it in a line from the centre of the portico through the statue, this line though not *quite* perpendicular to the plane of the portico, would have deviated from it in so *very slight a degree*, as not to be perceptible to the nicest eye, and would have obviated completely the very glaringly awkward effect of its present position, which, whether viewed as you turn up Whitehall or from the centre of the portico, is equally offensive to the eye, which would have been quite insensible to the very trifling deviation from the perpendicular in the line above mentioned.

ÆSTHETICUS —.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XXXIII.

—
 "I must have liberty
 Withal, as large a charter as the winds,
 To blow on whom I please."
 —

I. A "little bird" has reported to me that there have been sundry and several complaints, which complaints I am willing to accept as compliments. Never did I for a single moment imagine that my Note Book would be palatable to every body, being aware that it must, on the contrary, be unpalatable to a good many bodies, who, nevertheless, it seems, cannot abstain from reading it, notwithstanding that it is entirely optional on their part to do so or not. If those particular articles are not at all to their taste, why, in the name of common sense, do they not pass them over? They are no more compelled to read every column of every number of the Journal, than to wade every morning through the whole of the Times newspaper, advertisements and all.

They do not relish Candidus; so be it—I will not quarrel with them on that account; nevertheless, I merely say that at all events their dislike appears to be no more than a mere disliking, for which they either are unable or do not care to assign adequate cause, else wherefore should they be so forbearing as not to expose what they consider my errors and mischievous or unsound opinions. If my Note Book contains a good deal of "nonsensical stuff," its nonsense must at any rate be of a very attractive kind, since it compels them to read whether they will or no. Therefore, if it finds readers, both among those who relish, and those who disrelish it, I have no particular reason to be ashamed of it.

I suspect there is another and more powerful motive than mere dislike which makes my Anti-Candidus express themselves with a soreness and sourness. It is very true they themselves can skip over the offensive Fasciculi, but they cannot compel others to do so. Aye, there's the rub! They are frightened, lest other people should read—and perhaps have their eyes opened, by some of my remarks, to prejudices and abuses which they would have remain untouched, and to abuses they would rather screen than expose. No doubt there are some who, were it in their power, would suppress architectural criticism, and architectural journals likewise, altogether; and that for very sufficient and prudential reasons, as far as themselves are concerned. Well are they aware that the more the public are kept in ignorance of architecture, and the less any topics belonging to it are brought under discussion, the better for them. No doubt there are several worthy gentlemen who, if they durst, would protest against the exposures which have from time to time been made relative to mal-practices in competition; others, again, who think that it is high time for this Journal itself to be brought to a close. Such persons may not exactly be simpletons themselves—on the contrary, exceedingly wise in their generation; but assuredly they must take editors to be complete simpletons and noodles, if they suppose the latter will alter their places and arrangements according to the fancy of every body or any body who chooses to express a dislike to any part of them. Surely my Note Book is not so contagious as to infect with its virulence the whole of every number of the "Civil Engineer;" should it, however, really be so—in the opinion of certain people at least; such persons had better decline taking in the work. Awful would be the consequences—positively fatal to the publication; for our editor might then say, as H—the celebrated bootmaker is reported to have done, when a blustering consequential gentleman once threatened to deal with him no longer, "John, do you hear that? Tell them to close the shop windows directly. It is all up with us now—we are positively undone, for here is Mr. — going to withdraw his custom from us! But John, first of all open the door for Mr. —, and wish him a very good morning."

II. Among the odd "*They says*" of the day, it has been rumoured that the magnificent structure now building in Threadneedle Street is destined for nothing less than the reception of the Soanean Museum. That such must certainly be the case, is argued because no one can tell or possibly divine, what it can be intended for at all, if not for such purpose. Another cogent argument is derived from Sir John's well known attachment to the old lady of Threadneedle Street—her, I mean, who keeps the money-shop—and although these may seem very insufficient reasons, exceedingly vague and chimerical ones, far graver hypotheses have been hatched into systems all-compact, out of hints and surmises equally visionary and fantastical. It

will be objected that the Soanean Museum must not on any account be removed from the house it now occupies—but then there is not the slightest necessity that it should be, since house and all may be removed from Lincoln's Inn Fields to Threadneedle Street—a mere step of way compared with the distance a house once travelled to Loretto—and be commodiously enough placed in one of the spacious halls within the new structure, without undergoing any Procrustean operation. Though small as a house, it will cut a very respectable figure stuck up in a room as a model. It may, indeed, further be objected—however, I cannot stand to knock down objections, like nine-pins, as fast as people choose to set them up, therefore must be allowed to cut them short by calling upon any body who thinks himself capable to start some more *ingenious* ideas than my own as to the proposed destination of the building in question.

III.—Travellers have undoubtedly the privilege of romancing—that is, of lying, including a little blundering also; but when Mrs. Abigail Adams says that Canterbury contains "*a number of old cathedrals*," she does avail herself of the traveller's privilege rather too freely, and indiscreetly also. Perhaps the good lady "*saw double*" at the time, and seeing two cathedrals, multiplied them into a "*number*." Another no less extraordinary blunder occurs in a very recent German work on St. Petersburg, in which the writer has confounded the Kazan *Sobor* or Cathedral with the new St. Isaac's church, and has made the whole account a continued blunder, for he has gone describing and criticising the former building, mistaking it all the while for the latter; which is the more unaccountable, because the last, which is hardly yet terminated, happens to be just now the great architectural lion of the Northern capital. It is as if any one should mistake St. Paul's for the new Houses of Parliament, and describing the latter as having been erected by Sir C. Wren, speak of their noble dome. In one of the volumes of Lardner's Cyclopædia, Covent Garden Theatre is said to be a specimen of Grecian Ionic architecture, while the Post Office is similarly metamorphosed into one of Grecian Doric—which proves that if Doctor Diogenes Larnedman, as Fraser calls him, was not a downright humbug himself, that he certainly employed literary ignoramuses and humbugs to manufacture some of his books.

IV. "*Love at first sight*" is not always to be relied upon—at least not in architecture; there are many productions, whether buildings or designs, which captivate the eye at first view, yet sadly disappoint us when we come to examine them, or after we return to them. One almost infallible test of merit in art, that after the interest of curiosity has subsided, a work will not only continue to captivate, but that beauties, at first scarcely noticed, make them felt more and more. It would be well were every architect to apply such test to his own designs and studies, to examine them scrupulously, after laying them aside for awhile, for the purpose both of ascertaining whether they satisfy him in his own mind as well as they did at first, and of considering how they might be further improved. Invention and fertility of imagination may do much, they indeed furnish the ideas upon which to work, but the great secret of perfection lies principally in the careful study of the whole, and no less carefully finishing up of every part. The "*slap-bang*" school are above all such dilatoriness and trouble, they do not stand upon trifles; with them every thing is hit or miss, they never blot, they never revise; it is always "*first come, first served*" with them; they consider it loss of time to wait for a second idea. They are worse than bears, for they do not even care to lick their own offspring into shape.

V. The character of the "*celebrated Mr. Compo*," in the tale entitled "*St. Antholin's or Old and New Churches*," is by no means an over-drawn caricature. The cheap-church mania has afforded employment of late years to a good many Mr. Compos, manufacturers of Brummagem Gothic, or Brummagem Grecian—tasteless noodles in themselves, but who find still greater noodles who patronise them. The Compos may be said to be what is usually termed "*a fine family*"; they spring up like mushrooms, although very few of them ever *vegetate*. There is a church now going on somewhere in town, which, it is to be feared, will turn out a very Mr. Compo-ish affair, a most dainty specimen of Brummagem Gothic. The necessity for strict economy may be sufficient excuse for plainness, but none whatever for the insufferably vulgar taste and paltriness displayed in many structures of the kind. Where the funds are so beggarly that nothing can be done, the most advisable course would be to attempt nothing beyond bare walls and a roof. Homeliness may be endurable, nay, even respectable, whereas the miserly show of miserable trumpery finery, of which many new churches are instances, is so far from being respectable, that it is almost indecent.

VI. Speaking of the recent competition for the Devon Lunatic County Asylum, the Western Times expressed the hope that there would be "*a public exhibition of all the designs, according to established custom in all archi-*

lectual competitions"! Unfortunately, the established custom is exactly the reverse of what the Western Times, in its simplicity or its ignorance, has conceived it to be. Any exhibition of the kind at all is quite an exception from the general rule, the established custom being not to allow the designs to be seen, if it can possibly be avoided; because, if they are, the comparisons made, and the opinions expressed, may be any thing but complimentary to the judgment and taste of the selecting committee. The public is a strongly inquisitive animal that, if not prevented, would be poking its nose in everywhere. It is an impertinent, busybody, mischief-maker, that would fain pry into all the arcana of competitions, and the ingenious secret manœuvres and plottings of those who manage them. In short, the public is such a profane beast, that I wonder no one has contrived some mode of knocking it on the head at once. It is, therefore, to the honour of competition committees they do their best to get rid of it.

VII. "*Où la vertu va-t-elle se richer!*" was the exclamation of Molière on one well known occasion; and, substituting *virtu* for the other word, it was mine a few days ago, on quitting a bookseller's shop where a gentleman had been purchasing some very costly foreign works on art. "You have there a most excellent customer," said I, after the stranger had departed; "pray who may he be—is he a professional man, or some wealthy amateur?" "Perhaps you will be somewhat surprised when I inform you that that gentleman is no other than Mr. ——— of Fleet Street." "What! the same who keeps the ——— shop there?" "The same." "And does he purchase many works of this description?" "Yes; he is a very different customer from Mr. ——— whom you saw here the other day, a bachelor with twenty thousand a year, and who has somehow got the reputation of being a person of great taste, an admirer and patron of the fine arts; yet, as you saw, stood haggling about a two guinea book, which he has not yet made up his mind whether to have or not. But perhaps," added my friend somewhat sarcastically, "as he has got the reputation for being a very great amateur of the fine arts, he may as well keep his cash in his pocket." "Hang him for a hypocritical curmudgeon! But I hope you do not find many of his stamp." "More, I am sorry to say among persons of that class, than would be generally supposed." "Yet among professional men of the wealthier sort, you must sell a great many foreign architectural works." "There, I assure you, you are quite mistaken; I have hardly a customer of the kind. There is Mr. ———, Mr. ———, and Sir ———, all of whom it might be supposed would liberally encourage and subscribe to every architectural publication of importance, yet I have heard that they never buy a book at all, though they are by no means backward—two of them, at least, in *borrowing* them if they can." "Then the greater asses those lenders who accommodate such niggardly, skinflint borrowers. Such fellows would not be ashamed to borrow a dinner, and then return it *second-hand*. Do you find the nobility buy many books of the kind?" "I have very few indeed of them ever come here. My best customer of that kind is a lady—the Countess of ———, to whom I have sold a great many French and German architectural publications." "And the British Museum? inquired I. "Why, Sir, as to the British Museum, that, I suppose, you can answer for yourself. I dare say you know tolerably well what works of the kind are *not* to be found there." "Indeed I do; and know that while that national concern seems to be a repository for all the accumulated rubbish of our national *literature*, it is most shamefully defective in modern foreign publications on architecture and art generally.

HINTS ON ARCHITECTURAL CRITICISM.—PART 4.

THE RECAPITULATION.

To reduce the foregoing observations into order: we discover architecture to be highly poetical, first, from the suggestive power which she exercises, that is, from her ability to move us towards some idea of beauty, or sublimity, by attitude, or the expression of forms, as also by relative position; and secondly, from her independence of mere proportion, which is essential only to delight, or that satisfaction which may or may not create delight. It will be seen further, that no attempt is made to trifle with constructive talent, nor to infringe on the properties and harmonies of proportion, the former of which may still be scientifically viewed, and the latter agreeably entertained: but it will be seen, that, for the purposes of criticism, architecture has been viewed as a fine art, and that as such, her power over the emotions has been briefly considered to support her claims to the rank of a fine art. We perceive that poetry does not necessarily imply imitation, but that arts which are not descriptive, or imitative, may induce emotion. It would be unphilosophical to retread ground, further to confirm what has been assumed, but it

may be here remarked that compositions very often maintain their influence by the indistinctness of the idea they foster, and that what is so remarkable in poetry, viz., the sign of the effect, instead of the sign of its cause, being the origin of emotion, is also applicable in a similar way to architecture. The poet struck with some sublime idea, often paints the idea, rather than the cause of that idea, and this it is, which makes some of the denunciations of prophetic poesy so overwhelming: the mind having no definite idea of woe, but on the contrary:—and the cause is obvious, for the feelings of a poet being stronger than his reason, and those feelings being uppermost, he expresses *them*. Hence arises the power of poetry, which is never truer than when it exhibits its effects upon a mind. In the following passage from Isaiah, nothing can be more effective.—"*The noise of a multitude in the mountains, like as of a great people, a tumultuous noise of the kingdoms of nations gathered together; the Lord of Hosts mustereth the hosts of the battle.*" Here we have grand and mighty images, engulphing our reason;—confusion of noises, and multitudes, and great people—*tumultuous noises, kingdoms of nations—the Lord of Hosts—the hosts of the battle*. No one I think will contend against the poetic grandeur of such a description, if description it may be called, yet where can be found any thing about it, to give an adequately clear idea, of the movements of the Almighty, by whom, as Lord of hosts, we are arrested: we go indeed almost beyond the pale of nature by contemplation. I quote in this ~~passage~~ from holy writ, not for the purpose of allowing the sublime images of the bible, to become the pivot of an argumentative treatise upon the power of art, but to show the origin of our emotion. Now in architecture, many a man has felt something of this, when entering the cathedral; and this does not arise from our love of antiquity, which is quite different in its effects, and which I will hereafter try to make clear, but from the mysterious union of vastness and of infinity, of obscure images and of intricate beauties, amidst which reason is overwhelmed. So that, in judging of poetry, we very often judge of the emotion, and pronounce a composition as being good, or bad, according to whether the state of mind it is intended to plunge us into, is evenly, or unevenly sustained:—and this is essentially the province of criticism. And here I cannot help noticing the opinion which many entertain, of any attempt to reason philosophically upon works of art, in supposing that the promoter of such an attempt, is necessarily trying to lay down some fundamental law, by which the artist is to be ruled. It is impossible for any one, however vast his mind, or delicate his perception, or care, to regulate the artist in his choice or adaptation of materials, because the relations of a composition vary to infinity, and the mind, which could conceive a code of laws, would have to anticipate every possible relation. Criticism undoubtedly tends to invigorate and chasten, and one of the signs of refinement in any art, is the pure language and sentiment of its critics; but criticism is no more than an echo of sensibility subdued into a whisper, or swelling into praise, according as the judgment admits by degrees the full force of a composition. And all this accords precisely with a true definition of taste, for the degrees of difference between the opinions of a polished and an unpolished age, are, as the power of perceiving the influence of associations upon the mind. For be it remembered that the influence of associations varies, with our improved ideas concerning them; whilst a composition is not always judged by the intrinsic features of design, but by the ideas current concerning those features, and by the activity or stagnation of those ideas. Any one who has seen specimens of Indian carving, must have been struck with their representation of God, which they contrive by imitating no one thing, but by mixing what Horace ridicules in his art of poetry. Now they admire what we condemn and ridicule. We criticise their most adored objects of art by a smile, because our ideas of that awful being tell us that no attribute of his is exhibited. Had any barbarian of old exhibited his design to an Etruscan, in the days of Zeuxis, how would the Etruscan, versed from divination in forms, have smiled if the design had represented a group of animals? Just so is it with architectural criticism, which scarcely out of its cradle, begins to feel shocked at the vulgar opinions of cotemporaries, and this is the point I wished to arrive at, viz., to show the necessity to lay down some general idea of the duties of a critic, and of the vast field over which his sensibilities and judgment must move. I am aware that against such an attempt there are two objections; first, from the nature of the employment, which generally raises up an army of critics, like gnats to sting secretly and on the wing; and secondly, from that dearth of genuine poetry amongst us, which begets indifference to such themes; but I still hope to contend for the duties of criticism, satisfied that though such attempts be ridiculed now, they will not be hereafter.

FREDERICK EAST.

December 1841.

ON ARCHITECTURAL PRECEDENT.

No two classes of men appear to have so great a respect for precedent as lawyers and architects; by the one it is looked upon as of more importance than equity, and by the other it is appealed to as being a greater authority than any abstract principles of beauty or fitness; a judgment biased by the errors of our ancestors is considered as the best guide for conduct in modern times by the lawyer, and the architect uniformly persists in copying the designs of the ancients, however unsuitable they may be to the habits of the present day.

The universality of this prejudice in the case of the architect is evidently attributable to the system adopted in his education. A youth is taken into an architect's office, and the first principle of any importance that he learns is that "it is impossible to excel the ancients, and that the only thing we moderns can do is to copy their works;" he sees all around him engaged in making designs in accordance with the good old patterns, and is perhaps himself chiefly employed in preparing enlargements after some of the ancient examples: no natural taste that he may have for ornamental designing is checked, by telling him that he will never be able to come up to the works of our predecessors, and that he would be employing his time much better in studying the precedents handed down to us. The consequence is that he gradually imbibes the same veneration for antiquity that influences his seniors, and at the termination of his pupilage, instead of having had his natural creative talent brought to some perfection, he is probably as little capable of *originating* anything worthy of admiration as he was at the time he was articled; and he commences his professional career with the same determination to adhere to classic precedent that characterised his instructors; and this resolution being the result of a prejudice implanted in youth, is rarely to be removed by any arguments that may be adduced.

Surely it is sadly derogatory to the dignity of the profession, to have to acknowledge, that out of all the arts practised by the moderns, architecture forms the only case (with the exception of sculpture), in which the ancients have not been far outshone: such a conviction in the mind of an architect is certainly rather in consonance with due respect either for himself or for his employment.

Is it then to be wondered at that there should be that want of public respect towards the profession frequently complained of by architects? Is it likely that society should entertain any high veneration for an art whose very professors acknowledge themselves to be mere copyists?

Many persons will say that painting should be included amongst the arts in which we have not excelled the ancients. Perhaps in no one case is the notorious gullibility of John Bull more glaringly instanced than in the almost universal veneration for old pictures; every one sets himself up as a critic in such matters, even though he never made use of a pencil or brush in his life, and if a specimen coming under his notice happens to have the appearance of age, it immediately elicits great approbation, probably expressed in a string of cant phrases, which he recollects to have heard used on similar occasions: if however any attempt be made to ascertain the meaning of these expressions, the interrogator may consider himself clever if he can identify any ideas attached to them; not one in fifty who affect to be judges of the old masters can really give any sensible reasons for the preference he pretends to have for their works.

The public generally are aware of the advantage continually taken by picture vendors of this undue devotion to what is old; it is almost their everyday practice to secure some of the more spiritless of the modern paintings, and after having hung them for some time in a smoky room, and otherwise disguised their juvenile appearance, to palm them off upon these pseudo-connoisseurs as being some of the finest works of the old masters.

And yet notwithstanding the notoriety of this practice, and the conclusive evidence it affords that a great part of the supposed superiority of the old paintings is chimerical, the prejudice of society in their favour appears to be nearly as strong as ever.

The permanency of colouring, and the transparency of shade appear to be the only points in which we have been really excelled in this art by our ancestors. These are certainly two very desirable qualities, and their attainment is well worthy of attention, but after all they merely appertain to the mechanical department; the mixing of colours that shall be the most stable or the most transparent, can hardly be put upon a par with purity of artistic feeling or excellence of composition; surely the mere technicalities of the art are not to be compared with the grand imaginings of a Martin, or the exquisite truth of a Landseer.

The fact is that this affected admiration for the productions of our forefathers is only another development of that most abominable of maxims "*do as the world does*." men mixing with society find it the custom to enlarge upon the inferiority of modern art, and to laud the ancients, and even though they may have sufficient taste to see the injustice of the censure, they acquiesce in the opinion rather than endure the sneers of their associates.

But to return.—In attempting to prove the possibility of improvement upon the architecture of former ages, I am triumphantly met by an opponent with the fact that there *have* been men who scorned to follow in the beaten track; who have struck out a new path for themselves, and have attempted to originate new styles but have signally failed. Now what is there to be surprised at in this? Is it likely that out of all the architects existing in England, that the man who happens to be the most independent and liberal minded should of course be the one best fitted to carry out his views, and to compete with the combined efforts of the ancients?

Is it likely that amidst all the opposition of the admirers of antiquity, the prejudices of the public, and the jeers of the profession, that he should succeed in his endeavours? Is it probable that when generation after generation have been engaged in servile copyism, and that all exercise of original taste has been discouraged under the belief that it was impossible to excel, that a man should spring up who should at once be able to vie with the efforts of those whose forefathers had been in the continual exercise of their powers of design? The faculty of creating new forms is obedient to the same laws that govern the other attributes of the mind, and is only to be developed by constant practice, and the transmission of the talent from father to son; and if this talent has been allowed to lie dormant for generations, its power will gradually be reduced, in accordance with the same law that what is no longer exercised to the same extent, no longer retains the same capability.

There is then no ground for surprise that the architects of the present day should be unable to produce any thing superior to what already exists; it is even probable that if they were unanimous in attempting to originate, they would all fall short of what has already been done: but what would that prove? not that it is impossible to fix up a higher standard than that hitherto attained, but simply that the faculty of design requires redevelopment, having lost ground from want of practice during the latter ages. In short to use something like a truism, it is evident that so long as architects retain the belief that they cannot excel the ancients, they never will.

The influence of precedent has been much increased by unfair criticism; it has been the universal custom to enlarge upon all the beauties of the old buildings, and to pass over all the defects, and on the other hand all the imperfections of the modern ones are sought out and magnified, and all the merits passed over as unworthy of remark. The fact is that to an unprejudiced eye there are in many ancient examples far more glaring errors than in any modern buildings of the same character. For instance, if I recollect rightly, in the nave of Gloucester Cathedral, we have ranges of plain and massive Norman columns supporting small circular Norman arches, producing the impression of great stability, and then we find the adjoining aisles lighted by pointed Gothic windows, with all the usual characteristic lightness of this style of architecture. What can be more inharmonious than such a mixture? If one of the moderns had perpetrated such an incongruity, his reputation as a man of taste would have been irrecoverably lost.

Again, if one of the profession of the present day, a little more liberal than his brethren, happens in making a design in accordance with the style of some particular period, to introduce an ornament which was only used at some other era, although all the architects in England should not be able to offer any cogent reason why it should not harmonise with the other features of the building, he is at once sneered at by the critic, and stigmatized as a man of no purity of taste. But on the other hand if there should chance to be in the elevation of some cathedral a range of Gothic windows with angles of half a dozen different degrees of acuteness, producing evident want of unity in character, and any one draws attention to the fact as a great defect, the case is quite different—Oh, no! this is one of the works of our great ancestors, and we must not dare to criticise the designs of such superior men.

It is much to be regretted that such erroneous impressions respecting the ancients and their works should ever have crept into society: that same veneration for antiquity, is one of the greatest obstacles, not only to the advancement of architecture, but to the progress of every species of improvement. Perhaps no more effectual method could be adopted to lower the dignity of mankind, and to reduce the general tone of society, than to spurn the doctrine of the superiority of our predecessors: no method better calculated to produce want of confidence and consequent danger of incapability,

than to instil the belief that we have retrograded instead of advanced. And then to find not only that the impression is utterly erroneous, but that the truth is directly the reverse, and that the veneration of society is directed towards a people of whom it has been lately said by a talented author,* that "their history is a fable, and their philosophy a farce," makes the case still more to be deplored.

Perhaps it will be asked—how should this belief be so universal if it is without foundation? a very sensible question, but one to which there is no difficulty in finding an answer, and I may remark that the same cause that induces the feeling in society generally, is the origin of the predisposition of the same character in the architect. That cause exists in the present system of classical education.

H. S.

Derby, Dec. 15, 1841.

SIR FRANCIS CHANTREY.

THE life of a man of genius, passed in the study, observes a celebrated writer, has few incidents but the production of his works, and in no case is this more true than in that of the distinguished sculptor whose loss to art we have to lament. Truly English as he was in his style, he had much contributed to the formation of the present school of art, at the same time it must be observed that his addition to portraiture and neglect of the imaginative has not been without its influence in impeding the progress of high art. Under all circumstances, too, and considering how his chisel has been employed in celebrating the greatest men of the age, and how his works are distributed over every part of our vast empire, the name of Chantrey is indissolubly attached to the literary and artistical history of the age.

Francis Chantrey, the son of a farmer in Derbyshire, was born at Norton, a village in that county, on the 7th of April, 1782. Having been intended for the legal profession, he was taken to Sheffield to be articled to a solicitor, when a casual circumstance directed him to that career in which he was ultimately destined to attain so much honour. Having arrived before his friends, he was walking through the streets, and looking in the shop window of a carver and gilder, he felt such a strong bent for art, that he prevailed on his relations to apprentice him to the proprietor of the shop, a Scotchman of the name of Rogers, with whom he remained three years. Carving on wood, it is observed, was not his bent; before he was seventeen, he had applied himself to modelling in clay, and devoted his nights to that study. Having left the carver, he successively visited Dublin and Edinburgh, but not meeting with encouragement in either city, in 1808 he made his appearance in London, and soon found, in the exhibitions of the Royal Academy, the opportunity of making his genius known. A bust which Chantrey sent to the Academy attracted the attention of Nollekens, who, with his love of kindred art, exclaimed, "That's a splendid work, let the man be known; remove one of my busts, and put this in its place, for it well deserves it." The words were prophetic: the bust that of John Raffael Smith, was generally admired, and Nollekens, pleased with its success, took the artist under his protection, saying often to his friends, when applied to on the subject, "If you want a bust, Chantrey's the man." The late Earl of Egremont was another of the young artist's early patrons, and gave him a commission for the execution of a work in marble, but so rapidly did Chantrey's practice increase, that the work was never executed.

Early in his life Chantrey is said to have visited the Louvre, and inspected the magnificent collection of works collected by Napoleon from all parts of Europe. In 1816 our artist was elected an Associate of the Royal Academy, and in 1817 it was that he exhibited the celebrated group called the "Sleeping Children," erected in Lichfield Cathedral in memory of the two infant children of the late William Robinson. The homage paid to this work has been great, for when exhibited, young mothers are said to have wept over it, so affecting was the expression; for this work Stothard furnished the design. In 1818 he was elected a Royal Academician, and exhibited another well known work, the statue of Lady Louisa Russell when a child, now at Woburn Abbey. In the following year Chantrey visited Italy, and we find, among his works, a statue of Dr. Anderson executed for Madras, and monuments to Kirke White, Porson, and Fox Townsend at Cambridge. Chantrey, it may be

observed, was much employed for India, many of his largest works having been executed for the three presidential cities. He had now a very great share of the public business, and a curious anecdote is told in relation to this. Handling the brush as well as the chisel, Chantrey sent in such a model for the George III. statue for Guildhall, that the wise men of the east intended to reject it on the supposition that the artist was a painter; and it was not until Sir W. Curtis sent for him to be examined on this point that the preference was given to him.

In 1820, 21, 22, and 23, we find few important works exhibited in the Academy, but his chisel was far from idle. In 1824 he exhibited his statues of the Countess of Liverpool and Dr. Cyril Jackson, but in the next year his name was wanting in the catalogue. In 1826 he began casting in bronze, and we find, among his works, bronze statues of Pitt for Hanover Square, Grattan for Dublin, and George IV. for Brighton, Windsor, and Edinburgh. He had also a commission from the United States for a statue of Washington. In 1827 he executed statues of Sir Joseph Banks for the British Museum, and Mr. Stephen Babington for Bombay. The only work exhibited in 1828 was a bust of Sir W. Curtis. The next year produced a statue of Sir Edward Hyde East, for the Court House, Calcutta, and a classical bas relief, and 1830, a statue of Bishop Heber. In 1831, he completed his statue of George IV. for Edinburgh, 12 feet high, and the coronation medal of William IV. and Queen Adelaide was executed by Wyon from his models. In 1832 he completed a statue of Canning for Liverpool, and in 1833 one of Sir Howard Elphinstone. From William IV. Chantrey received the honour of knighthood. In 1834, 5, 8 & 9, Chantrey did not exhibit, but in the intervening years he exhibited his statue of Sir John Malcolm, and one of Dr. Dalton. In 1840 our sculptor produced statues of William Roscoe, and of Northcote, the painter, and of Sir C. Forbes, and also an equestrian one of Sir Thomas Munroe. In the present year only two works were exhibited, namely his statues of the late Bishops of Norwich and Lichfield, executed for their respective cathedrals.

On the 25th of November, having only returned on the day before from a visit to the Earl of Leicester at Holkham, he died at his house in Eccleston Street, between eight and nine o'clock in the evening. In the morning he was in his usual spirits, inspecting the progress of the various works in his studio, and conversing cheerfully with his assistants; but during the day he had complained of illness, and had been compelled, by violent pains in his stomach, to return from Buckingham Palace, whither he had walked in company with a friend. He then received some medical advice from which he obtained relief. At seven he dined moderately as usual with a small circle of friends; but feeling unwell, he sent for a medical man, who directly required the attendance of his physician; but before the arrival of Dr. Bright Sir Francis breathed his last, it is supposed from apoplexy.

In person Sir Francis was under the average height, possessing a compact form and a highly intellectual countenance. He drew with taste, and engravings from his views in Dovedale were published; he was also an admirer of less artistic pursuits, having recently purchased a large geological collection for five thousand pounds. In his studio he possessed all the resources for carrying out great works, having for his assistants Allan Cunningham, who had been with him 28 years, Mr. Heffernan 30 years, and Mr. Weeks, and possessing a regular establishment for casting in bronze. He had in hand an equestrian statue of the Duke of Wellington, which is in a forward state, and he was appointed to execute the statues of Sir David Wilkie and Mrs. Siddons. Sir Francis Chantrey was a Royal Academician, Member of the Academies of Rome and Florence, and a Fellow of the Royal Society. He was married, and has left a widow but no children; his large fortune he is said to have bequeathed, after his Lady's death, to the Royal Academy, to be devoted to the promotion of the arts. Of him it may be truly said, that his good deeds will survive him, and that his fame and good report will live for ever.

Of his works we have not yet seen any complete catalogue, but will endeavour to furnish one as copious as our materials allow, with the dates of exhibition and places in which preserved.

Equestrian statues:—Wellington (Mansion House, not completed); Sir Thomas Munroe (Madras, 1840).

Statues:—George III. (Guildhall); George IV. (Brighton, Windsor, and Edinburgh); Washington (United States, 1826); Pitt (Hanover Square)

* Philosophic Nuts, by Edward Johnson.

Grattan (Dublin, 1826); Canning (Town Hall, Liverpool, 1832, Westminster Abbey); Nelson, Dr. Dalton, Bishops Heber, (St. Paul's), Bathurst (Norwich, 1841), and Ryder (Lichfield, 1841); William Roscoe (Town Hall, Liverpool, 1840); Watt (Westminster); Nollekens (1840); Sir Joseph Banks (British Museum, 1827); Sir J. Malcolm (Westminster, 1837); Sir Howard Elphinstone (1833); Sir Edward Hyde East (Court House, Calcutta, 1829); Dr. Cyril Jackson (Oxford Cathedral, 1824); Countess of Liverpool (Kingston Church); Lady Louisa Russell (Woburn Abbey, 1817); Dr. Anderson (Madras, 1819); Marianne, daughter of Mr. Johnes of Stafford; Mr. Balmington (Bombay, 1827); Sir Charles Forbes (Bombay, 1840).

Monuments:—Sleeping Children (Lichfield, 1817); Majors General Gore, Skeritt, Bowes, and Hoghton, and Colonel Cadogan (St. Paul's); Matthew Baillie (Westminster Abbey); Admiral Bickerton (Bath Abbey Church); Mrs. Elwin (Bristol Cathedral); Kirke White, Porson, and Fox Townsend (Cambridge).

Busts, see Statues. Also William IV.; Queens Victoria (1840) and Adelaide; Duke of Sussex; Princess Louisa of Saxe Weimar (1833); Duke of Sutherland (1829); Marquis of Londonderry (1821); Earl Spencer (1819); Lady Nugent (1820); Viscount Melbourne; Lord St. Vincent; Southey (1837); Scott; Sir Jeffrey Wyatville (1837); Sir John Soane (1830); Horace Hayman Wilson (Asiatic Society, 1837); Mrs. Somerville (Royal Society, 1837); John Raphael Smith; Wordsworth; Sir W. Curtis (1828); W. Manning (1819); Sir B. Hobhouse (1819); John Fuller, (1820); Sir Charles Clarke (1840); Dr. Mill (Asiatic Society, Calcutta, 1840).

The Waterloo Vase in the National Gallery is also by Chantrey.

DANNECKER THE SCULPTOR.

On the 8th October last, died at Stutgard, after a short illness, the well-known John Heinrich Dannecker, the Nestor of German sculptors. He had but a short time previously completed his 84th year. Stutgard was his native town, where he was born on the 15th of October, 1758, of poor parents. In spite of the disinclination of his parents, he determined, when very young, to turn his attention to the plastic arts, and by a personal application to Duke Charles of Wurtemberg, in whose stud his father was employed, he succeeded in gaining admission, in 1771, to the military artistical academy at the "Solitude," a Royal castle near Stutgard, where pupils were instructed free of expense in music, painting, and sculpture. The instruction he received here, however, was but a faulty one. It was in his 16th year that he carried off the prize for a model of Milo of Cortona. He next executed the Caryatides and other statues which at present adorn parts of the Royal residence at Stutgard. It was while studying in this academy that he made the acquaintance of his fellow-townsmen Schiller, and of this friendship a lasting monument remains in the statue, which he afterwards took from life, of the illustrious poet. He left the academy in 1780, at the same time as the poet, and attained the situation of Court sculptor, with the paltry salary of 300 florins, or about 25*l.* per annum. The following year he was permitted to visit Paris, receiving, however, no further pecuniary assistance than that his salary was raised in the second year of his absence, to 400 florins.

At Paris he met with the sculptor Scheffauer, and became a pupil of Pajou. While in the French metropolis he devoted himself more to the study of nature than that of the antique models. In 1785 he left Paris with Scheffauer, with whom he travelled to Rome, where he became known to the immortal Canova, whose friendly instruction had a very beneficial influence on the youthful artist. It was here, too, that he made the acquaintance of Goëthe and Herder, then residing there in order to become acquainted with the stores of art which were contained in the Papal capital.

Whilst in Italy his excellent marble statues of Ceres and Bacchus first raised him to a greater reputation, and caused the academies of Milan and Bologna to choose him a member of their bodies. He subsequently returned to Stutgard, and was engaged for a long time modelling various subjects for Duke Carl. It was not till 1796 that he again began to work in marble, when he executed his celebrated Sappho, the original of which is now at Munrepos. After this and other ideal efforts he turned his attention to the taking of busts, and now it was that he took the likeness of Schiller before alluded to, a colossal copy of which graced his atelier. The then Crown Prince of Bavaria, now King Louis, employed him in various works, among which his bust of the celebrated composer Gluck is one of the most remarkable. The performance by which he is most known to the English lover of art is his delicious Ariadne as the bride of Bacchus, borne on a panther, which

is to be seen in the house of the banker Bethman, of Frankfort. His Eros at the moment that Psyche is pouring on his shoulder drops of burning oil, according to the well-known Mythus of Apuleius, is also a beautiful piece of design. His best bust is supposed to be that of the physiognomist Lavater. But the *chef-d'œuvre* of the artist is his statue of Christ, for the idea of which he is said to have been indebted to a nocturnal dream. The completion, which took place in 1824, has cost him eight years of study and labour. It was then sent to the Empress Maria Feodorovna, of Russia, who afterwards made a present of it to the Emperor Alexander. The successful manner in which he succeeded in exhibiting Christ as the Mediator, and the divine expression which he imparted to the forehead of the statue, have often been the theme of praise. Thorwaldsen, who saw the model in the artist's workshop, expressed his opinion that the design of representing the Saviour as fully clothed would be a failure; undeterred by this, however, Dannecker maintained his original idea, deeming this as the most fit manner of treating the subject, and he succeeded in giving to the flowing drapery which envelopes the form a degree of lightness and truth seldom witnessed.

Dannecker's style was formed principally on the antique. His compositions are full of truth, life, and nature. His most distinguished pupil is Martin von Wagner, Secretary to the Academy of the Fine Arts, at Munich. For some years he had ceased from all active employment, and had fallen into a state of second childhood and oblivion.

DR. BIRKBECK.

WHILE recording the death of Sir Francis Chantrey, we little expected to have so soon to chronicle in our obituary, the name of a professor of the useful arts. In Dr. Birkbeck we have lost a man who has greatly contributed to the progress of education among working men. Although several individuals preceded him in the attempt, Birkbeck must certainly be considered as the founder of Mechanics' Institutions.

William Birkbeck was a member of an opulent and respectable family of the north of England, belonging we believe to the Society of Friends, but which they afterwards left. He was the son of a merchant and banker, and born at Settle in Yorkshire, in 1776. Having studied for the medical profession in the first instance at Leeds, he came to London and became a pupil of Dr. Baillie, afterwards removing to Edinburgh to complete his education. At that university he became the friend of Brougham, Jeffrey, Horner and Scott, and having distinguished himself by his attainments, he was appointed in his 22nd year Professor of Natural Philosophy, in the Andersonian Institution of Glasgow. It was while fulfilling the duties of this appointment that Dr. Birkbeck laid the foundation of the system of Mechanics' Institutions, and in 1822 he founded the London Mechanics Institution, of which he was for nearly twenty years the President, and which he aided both by his influence and his purse. He died on Wednesday the 1st of December, of a severe protracted illness, lamented and honoured by men of all parties and all ranks. He was twice married and has left behind him a widow and five children, three sons and two daughters, one by the first, and four by the second wife. As a physician he enjoyed much reputation and considerable practice, but as a philosopher and a mechanic his abilities were not less eminent. Dr. Birkbeck's mortal remains were interred in the General Cemetery at Kensal Green, and were attended to the grave by the members of the Mechanics Institution and many hundred people.

MR. THOMAS STEVENSON'S IMPROVEMENTS ON LEVELLING INSTRUMENTS.

SIR—In last month's Journal I perused with interest Mr. Townsend's observations on my improvements on Levelling Instruments. His remarks are in general judicious, but he appears to have misapprehended the main object which I had in view, and in some places he has entirely mistaken my meaning.

The rod is only 12½ feet long, and not 25 feet as Mr. Townsend supposed, and is divided as the old rods used to be divided in Scotland, to 10ths, 100ths, and either by vernier or appreciation to 1000ths. The object aimed at by me therefore was not to attain greater accuracy in the graduation of the sliding vane rod, but simply to save time in the use of that instrument. "For," (as Mr. Simms observes in his excellent Treatise on Instruments), "it not unfrequently happened in using the old staves that when by a succession of signals the staff holder had nearly brought the wire of the vane to coincide with that of the telescope, he would in his attempt to perfect it, remove the vane further from coincidence than at first." To obviate this defect, as I formerly mentioned in my communication to the Institution of Civil Engi-

neers, I introduced a clamp to be used by signal when the cross hair of the instrument has been brought nearly to coincide with the centre of the vane, leaving the rest of the adjustment to be made with the screws. By this arrangement the great loss of time arising from the rough process of adjusting the vane by the hand is completely obviated, and the sliding vane rod, which is certainly the best instrument where great nicety is required, is thus freed from these objections. This instrument is therefore adapted to the most accurate purposes, always, excepting indeed researches such as those of Mr. Bunt, who read off to four places of decimals, while at the same time the self-reading graduation on the back of it renders it equally well adapted for every operation connected with engineering, and there is no reason, as Mr. Townsend seems to imply, why the readings should be pushed to a greater degree of accuracy than the wants of the observer, or the delicacy of his instrument may warrant.

With regard to the spherical or circular level which Mr. Townsend seems, so far as I can understand, to employ in a somewhat different way to me, I have to mention that my communication on that subject to the Institution is dated the 30th of January, 1841, although it was not read till the 4th of May. The great superiority of the spherical level as used by me consists in the *dulness of its motion*, a quality rendering it peculiarly fitted for the purpose assigned to it.

Mr. Townsend takes exception at the ball and socket joint, but I would observe that the surface of the ball which is in contact with the clamping zone is very considerable, and the friction produced so great that no unsteadiness is found to be produced by this construction in instruments for ordinary purposes. In such an instrument as a single second-level, which is only to be used for extraordinary purposes, I would not propose to adopt the ball and socket, as any method for saving time in setting such an instrument is of no value. In such a question as this, *experience is everything*, and I have to state that having now used that instrument on some 40 or 50 different occasions, I cannot forget the great facilities it has afforded, and the time it has saved me, more especially when a rising tide rendered time of paramount importance. I firmly believe that any one *after a day's experience of it*, would admit it to be the most desirable instrument he had ever used.

I remain, your obedient servant,
THOMAS STEVENSON.

Edinburgh, Dec. 10, 1841.

P.S. I do not consider it necessary to occupy valuable room in noticing the observations of Mr. Bewley.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

June 29.—HENRY ROBINSON PALMER, V. P. in the Chair.

The following were elected:—George Briant Wheeler Jackson, as a Graduate; William Crellin Pickersgill, William Millar, Robert Cantwell, Thomas Clark, and Hugh Roland Labatt, as Associates.

"Description of the Bann Reservoirs, County Down, Ireland." By John Frederick Bateman, M. Inst. C. E.

The construction of the reservoirs described in this communication was undertaken with the view of regulating the quantity of water in the River Bann, and more effectually supplying water power to the flourishing and increasing establishments on its banks; this river is, from the bare and naked character of the Mourne Mountains, among which it rises, naturally liable to the greatest irregularity in its volume; devastating floods frequently pour down the channel, where a few hours previously there was not sufficient water for agricultural purposes: greatly injurious as this must have been to the agriculturist, it was infinitely more so to the mill-owners, who depended entirely upon water power for their manufactories.

Mr. Fairbairn was consulted on the subject; he examined the locality, and advised the formation of reservoirs: the author was then appointed the engineer, and acting in some degree upon the suggestions of his predecessor, whom he continued to consult, the works were undertaken which are described in the present paper.

The peculiarities in the act of parliament, granted in 1836, constituting the proprietors of the mills a Joint Stock Company, for the formation of the Bann reservoirs, are detailed.

The works were originally intended to have been more extensive than have been really executed. The reservoir at Lough Island Reavy, is alone described: the ground in that spot was admirably adapted for the work, being the bottom of a basin, which was bounded on all sides by rugged hills of granite; in the centre of the basin was a small lake, at the bottom of which was discovered a bed several feet in thickness, of fossil *conferve*, similar to those discovered by Professor Silliman at Massachusetts, North America. This interesting geological fact was first noticed by Dr. Hunter, of Bryansford; the *conferve* appeared like an impalpable powder, but when viewed through a powerful microscope, they were found to be regular parallelograms, many of

them covered with striæ. They are described by naturalists as the fossil skeletons of minute vegetables.

The situation fixed upon for the reservoir, rendered necessary the construction of four embankments between the hills, so as to raise the water to a height of 35 feet above the summer level of the lake.

These embankments were all constructed in a similar manner, only varying in the slopes and thickness of the stone facing according to the extent and situation.

The whole substratum of the valley was water-tight, either from the existence of the solid rock, dense clay, or of hard, compact, mountain gravel; so that there was no difficulty in securing the foot of the puddle. A trench was sunk into the water-tight stratum, whence the vertical puddle wall was carried up with the bank to the required height. It was 12 feet in width at 40 feet below the top, diminishing gradually to 8 feet wide at the summit, and was worked in regular layers of 8 inches in thickness.

The embankments were formed in concave layers 3 feet thick, each layer being completed before another was commenced, steps being cut in the ground where necessary, to receive the layers.

In order further to secure the tightness of the bank, a lining of peat 15 inches in thickness was brought up on the inside of the puddle, and a layer of the same material was laid upon the face of the slope; it was cut small, placed in thin courses like the puddle, and merely trodden down without more moisture than it naturally contained. The author advocates the use of peat in such positions, as, from its light and fibrous nature, in case of a leak occurring, the draught would attract into it all the fibrous particles, which by degrees would stop the holes sufficiently for the silt to settle over and effectually close the aperture.

Above the peat a course of gravel 3 feet in thickness was laid, and upon that the stone pitching, forming the inner side of the bank.

The inner slopes were for 20 feet below the top of the bank, $2\frac{1}{2}$ horizontal to 1 vertical; the outer were 2 horizontal to 1 vertical; where they were deeper than 20 feet, the remainder of the backs sloped 3 to 1 on the inside, and $2\frac{1}{2}$ to 1 on the outside.

All the embankments are 12 feet wide at the top, and 5 feet above the water level.

The centre of the deepest part of the embankment was traversed by a stone culvert, in which were placed two rows of cast-iron discharge pipes, 18 inches diameter, with suitable valves. A leak was discovered in the centre of the masonry of this culvert, occasioned by the engineer's instructions not being obeyed. The details of the methods employed for remedying this defect are given at length; as also those of the experiments upon cements made by the author after the data given by Vicat. The materials which were most accessible for the work were tested very carefully, and from the results, it was determined to employ mortar composed of rich Manx or mountain lime carefully slaked, and clay burned with peat in the open air. The proportions were $2\frac{1}{2}$ of clay to 1 of lime. They were ground together, and being mixed with as much water as was necessary, the mortar was used immediately. The mortar for the backing had one measure of sand added; the grout had two measures of sand in it, and was used thin.

The concrete was composed of one part of lime, two and a half of calcined clay, and about three parts of sharp gravel.

This cement appeared to set hard, and to be perfectly tight; but when the reservoir was partially filled, several leaks were discovered, which rendered an examination necessary, and some energetic measures were taken to stop them, all which are described.

The result of the author's experience seems to be, that mortar made from rich lime and calcined clay, as recommended by Vicat, may set and harden under water when there is little pressure, but that it is not able to resist the pressure of a considerable depth of water.

The details of the construction of the masonry of the valve house, the fore bay, the waste weir, the bridge of three arches, constructed over the feeder from the river Muddock, and the various feeders for supplying the reservoir, are given at length, with the particulars of the expenditure of the sum of £14,891, which was the cost of the work, exclusive of land compensation, or salaries and professional charges.

The particulars are also given of a series of observations with rain gauges continued for two years, for the purpose of furnishing data for computing the extent of reservoir which would be necessary to insure a supply of water throughout the year.

The communication is accompanied by detailed drawings of every part of the works, and a plan of the district in which they are situated.

"Description of a machine for sewing Flat Ropes." By Eugenius Birch, Grad. Inst. C. E.

In a previous communication, Mr. Birch described and gave drawings of the ingenious machinery invented by Captain Huddart: the subject was not entirely complete without the description of the present machine, which, although not of great importance in a scientific point of view, is well worthy of notice, in consequence of its being attached to this valuable rope machinery, and of its having been worked so successfully.

It is used for sewing or lacing together ropes, and forming them into flat bands, which are used for mining purposes, &c.

The bands or flats generally consist of four ropes, which are placed parallel to each other, and paired in contrary directions to the angle of the lay; being held under an equal degree of tension, they are sewn together with two cords

or lines, by needles which are driven through holes previously pierced in the ropes, at an angle of 45 degrees, and the cords are then drawn tightly in a lateral direction.

That the ropes may be pierced more easily, it is necessary that the tar which they retain from the process of warm registering, should be softened; this is accomplished by passing them through a steam chest, whence they are drawn into a frame composed of four plates, which are placed so as to compress the ropes while they are in the softened state, and form a die which can be regulated to the size of the ropes required to be sewn. The piercing operation is performed in the die, which has slots in its sides for passing the piercers through.

There are not any recorded experiments on the strength of the ropes, but it is considered, that the amount of strength possessed by the flat rope is not equal to the sum of that of the four ropes before they were united; still the advantages of this mode of assemblage are so great, as to insure its preference in running operations, and many other applications.

The drawings (which are numbered onward from the commencement of the set presented to the Institution, in the session of 1838*), display the entire machine, with details of all the parts.

END OF THE PROCEEDINGS, SESSIONS 1841.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

Dec. 6.—P. HARDWICK, Esq. R.A., in the Chair.

Mr. Hardwick opened the session by congratulating the members on the increasing interest shown in the proceedings of the Institute, and especially on the honour conferred on the Institute by His Royal Highness the Prince Albert, having graciously consented to become its patron, and on the arrangements which had been effected between the Committees of the Institute and of the Architectural Society, for a union of those bodies.—The Foreign Secretary, Mr. Donaldson, read letters from Sig. Clementi Folchi, of Rome, and Sig. Raffaele Politi, of Girgenti, acknowledging the honour conferred upon them by their being elected Honorary and Corresponding Members.

A paper was then read of the Great Pavilion erected at Liverpool, for the Royal Agricultural Society of England, by J. W. Wild. This paper will be found in another part of the Journal.

Dec. 20.—Jos. KAY, Esq., V.P., in the Chair.

Mr. Donaldson read a description of the Column erected on the Place de la Bastille, at Paris, to commemorate the last of the French revolutions, viz., that of 1830.

The evening concluded by a concise and interesting description of the Escorial, compiled by Mr. Hayward, the Librarian of the Institute, and illustrated by a large plan.—The Institute adjourned for the holidays, until the 17th of January.

ARCHITECTURE IN MANCHESTER.

WHILST in London we hear too many complaints of the profession being overstocked, in Manchester, where, during late years the number of architects has doubled, all seem to be full of employment. No doubt this excitement is but temporary, being caused by the exertions of a party, who, despite the very general depression in the manufacturing districts, have succeeded in raising funds towards the erection of ten churches, some of which are actually in progress. In addition to these are other churches and chapels, and some public buildings, but few private mansions.

The first church we shall notice is from the design of Mr. E. Walters, an architect of considerable talent, who to much scientific and practical knowledge, unites the feeling and nice perception of the artist. It is in Granby Row, and stands on ground descending at a considerable angle from the street to the river, the retaining wall of which is about four feet from the east end of the church. The architect has surmounted these obstacles; and though the foundations swallowed up the sum of £480, he is confident of being able to complete the church for £2400. It is to contain 800 people, 600 adults, and 200 children. The west elevation, which is all that is seen from the street, is of the early English style, and has been carefully studied. Mr. Walters is the architect of a larger church at Broughton Bridge, which is contracted for at £2950. The foundations had to be taken down to the depth of 12 feet. The church is built of brick and stone, and is in the Norman style, with two windows in each bay, whose heads are supported by shafts. The entrance door has Norman mouldings and shafts, and though with little ornament, is

very good. The architect has shown some skill in overcoming the difficulties of his roof, which is in one span, and without a tie-beam, stability being ensured by inserting concealed rods, which, passing along the timbers, retain the feet of the principals. The church will contain 1100 people. Messrs. Cuffley and Starkey are the architects of a church near Pin Mill Brow, which will cost £3000, and will contain 1150 people. The level of the ground being considerably beneath the road, brick piers were carried up to support the beams, on which is laid the floor of the church. The pews under the galleries ascend in steps from the passage, and each person will look towards the opposite side of the church, as in the galleries above. The style employed is Norman, and the tower will be surmounted by a low Norman spire. Messrs. Cuffley and Starkey are also the architects of a church in Regent Road, which is also Norman. It displays some novelty in its windows, but appears faulty in its details. Miss Atherton has provided the funds for a large church in the new Stretford Road, the competition for which was gained by Messrs. Scott and Moffatt, of London. Mr. Moseley, of London, has lately been successful in a competition for a church at Red Bank. Mr. Pugin is at present building a large Catholic church, in the township of Hulme, which we cannot too highly praise. It consists of clerestory and side aisles, with roofs of very high pitch, and we have heard that a tower is to be raised at the angle. Its exterior in the flanks is very plain, being of red brick and stone, with early English lancet windows placed singly, the opening of each being little in comparison with the extent of neighbouring wall, and with a north porch and a south door, having shafts and very beautiful arch mouldings. The east end has early English arches, and a circular window. The interior of the church charms by means of its elegant proportions, its altars, its piscinae, and other accessories of Catholic worship, which are here in all their integrity. We have heard some of those self-created critics who "rush in" with their opinions, though confessedly entirely ignorant of architecture, assert that the church was bad in design, that it was "like a barn." Oh! that instead of the paste-board Gothic of the church commissioners, we had some of those picturesque old barns. The Baptist chapel in the Oxford Road, just opened, is from the design of Mr. Walters. The sides will be enclosed by buildings, therefore enrichment is confined to the front, which is of stone, and in the early English rich style, with a centre door, over which is a two light window, the whole surmounted by the highly pitched gable and square pinnacles. The recess in the east, in which is the baptistery, is decorated with three early English arches. The whole was executed for £2300. These are not the only chapels in progress or just completed, but the others we were unable to visit. The Manchester and Birmingham Railway Station is a stupendous work, and has been performed with so great care, and with such good materials, that it may well last for centuries. It does not yet exhibit many of its decorative features. We noticed a building at the bottom of Market-street, which possessing some good points, is a glaring specimen of a bad modern mode of building. It fronts three ways, and the lower story is of shops, the ponderous superstructure appearing ready to crush the glass beneath. Leaving out of the question the bad effect of such a mode, it is positively insecure. The shrinking of timber bresssummers is one part the cause of the cracks, which disfigure our buildings—and in case of fire, the whole front becomes one general ruin. In this case little is got by using iron, for the beams having become heated, snap when played upon with water. The Independent College stands about three miles south west of the town. It forms three sides of a square, and is understood to have cost £14,000. The front has two stories supported upon an arcade, and a bold entrance door leading to a flight of steps by which the hall and principal floor are gained. Over the door is a fine Oriel, and above rises the tower surmounted by an octagonal lantern. The style is that of the latest period of Gothic architecture, and is well kept up through the whole of its details.—Mr. Irwin is also the architect of a building in Pool Fold, which has the superimposed orders of the late Elizabethan, or early Italian school. In the neighbourhood of Cheadle, Mr. Atkinson, now of London, is erecting some Italian lodges of chaste design. This architect, whom we might fearlessly place at the head of modern professors of the Gothic style, has enriched the neighbourhood of Manchester with its best buildings. His church at Cheetham Hill has been already noticed in this Journal:—we merely stop to praise the great beauty of its details, which will prove a mine of study to all who carefully examine them. The church at Openshaw is much plainer than, though scarcely inferior in effect to, that at Cheetham Hill. It is in the early English style, with arcades and windows in the clerestory, similar to those in Beverley Minster. At the west a lantern rises from the roof, surmounted by a leaded spire.

Whilst we were in Manchester, a paper by Mr. Goldsworthy Gurney, was read at the Victoria Gallery, and excited much discussion, the subject on which it treated—that of Heating by Hot Water Pipes—

having lately been much canvassed, in consequence of numerous fires having been ascribed to this cause. Mr. Gurney had found that it can be carried through the air along a pipe, a distance of forty feet, sufficient to melt lead, and that these results took place with the low pressure pipes. The safety valve in certain cases was no protection. On placing stop cocks at certain distances along a pipe communicating with a boiler, he found that when the temperature was sufficient to burn saw-dust, an invisible and inflammable elastic fluid escaped. He advised that six inches of the circuit in pipes for heating be made of lead.—A new cement has been used at Manchester called Lithic cement, it is as hard as stone, and has a face as smooth as earthenware. It would be useful in the metropolis where our cements scarcely merit the name. In architecture generally, we were glad to see a gradual movement onward, and though the progress is slight, it is of that kind which augurs well for its continuance.

December 1841.

REVIEWS.

Practical Essays on Millwork and other Machinery. By ROBERTSON BUCHANAN, afterwards improved and edited by THOMAS TREDGOLD, C. E., and now re-edited with the improvements of the present age, by GEORGE RENNIE, C. E., F.R.S., &c., 2 vols. 8vo., with numerous plates. London: John Weale, 1841.

THE name of Rennie would be embalmed in the history of millwork improvement, did it not possess still nobler claims to immortality. It was the father of the editor of the present volumes who first gave a real practical efficacy to those philosophical speculations which ascertained the true geometrical configuration of the elementary parts of wheelwork that was essential to produce uniformity of impulsive action and durability of operation. The millwork of the Albion mills was the first public manifestation of the late Mr. Rennie's abilities, and the improvements introduced by him upon that occasion gave an impulsion to millwright operations, such as the art had never before experienced, and of which it still feels the beneficial effects. It is little more than half a century ago that the teeth of all the millwheels in this country, with a few inconsiderable exceptions, consisted of nothing better than round wooden pegs. Smeaton accomplished some amelioration. But it was reserved for Rennie to give to millwheels their present form and structure, and the achievement would have been sufficient for his fame, had it not been thrown into the shade by those more brilliant triumphs of genius by which he is now almost exclusively remembered.

In opening a treatise upon millwright operations which has been published under the supervision of a son of this distinguished engineer, and who is himself already honourably known as a scientific and practical mechanic, our expectations were naturally commensurate with the auspicious quality of the circumstances under which the work had been produced. We cannot say that these expectations have been wholly disappointed. There is a considerable infusion of information in these volumes of the highest utility, and there is evidence of extensive erudition, and an intimate acquaintance with the subject. Yet the execution of the work is by no means satisfactory. There is a want of vigour and of unity discernable throughout the whole treatise—the needless prolixity of some of the chapters is extremely fatiguing to the reader—obscurity is not unfrequently produced by excess of simplification; and the arrangement, notwithstanding the exertions of an excellent analytical table of contents, is very much like the Gordian knot which no one can disentangle. We do not remember to have met with any work which required a more painful exercise of attention on the part of the reader, and this attention is not rendered necessary by the difficulty of apprehending recondite investigations, but by the difficulty of ascertaining the mutual relation of the several parts of the discourse—of unwinding the tangled thread of the enquiry. In fact these volumes can scarcely be regarded as a connected systematic treatise, they are rather a disorderly collection of miscellaneous papers of varying quality, from which the reader may make a selection, and which he must arrange for himself. In addition to Buchanan's original work with editorial notes and emendations, and two long papers in the form of appendices, besides supplementary definitions and other irrelevant matter, we have a vast number of "observations," "general observations," and "supplementary observations,"—the greatest part of them trite and trivial, mingling with the text, and dancing through every page in the most disorderly and fantastic array. The thread of the discourse is broken at every step,

and the reader is almost tempted to throw a work aside which demands a severity of labour that bids fair to rival the toil of Sisyphus.

Another source of considerable perplexity is the absence of all means of determining what portions of the work are due to the original author, and what to his respective editors. Additions and commentaries are mixed up without scruple with the original text, so that we are utterly at a loss to know, unless by a reference to previous editions, to whom we are paying attention. After having listened for some time to Mr. Robertson Buchanan, we find that by some undivulged metempsychosis, he has been for some time changed into Mr. Thomas Tredgold, or Mr. George Rennie. In page 5, for example, it is observed, "Were the teeth of wheels infinitely small, their action would be regarded as that of cylinders simply touching, having the property required. The finite and sensible teeth given to wheels will therefore be of the most advantageous figure when one wheel conducts another, as if they simply touched; or, when their pitch lines have in every part of their revolution equal velocities. That teeth have this property when formed in a certain manner will be evident from the following proposition and its connexions." This quotation we find by a note at the foot of the page, to be a part of Buchanan's text, and we naturally conclude that the text continues to be Buchanan's until we receive some intimation to the contrary. But we have not advanced above a dozen lines further before we meet, "Before proceeding with our author, it will be," &c., whereas we imagined it to have been the author himself; we had all the time been listening to.

At what point in the compass of a dozen lines Mr. Buchanan has been transformed into Mr. Tredgold or Mr. Rennie, we have no means whatever of ascertaining. We are unable to distinguish between what is said by the one person and what by the other person without collating the different editions—without, in fact, ourselves editing a book we merely wish to read. In page 26, we read, "To make that part of a tooth which is within the pitch line or proportional circle, a straight line as proposed by our author, seems to be the most advantageous form;" and in page 27, "When part of the action takes place before the teeth arrive at the line of centres, the method of forming teeth proposed by our author (Art. 41), seems to be equal, if not superior to any other;" yet the article from which these quotations are taken are a part of the text, in no wise distinguishable as such from Art. 41. In page 44, we find, "It has been mentioned to me that the following rule in order to determine the length of the teeth of wheels is employed by the ingenious Mr. Murray of Leeds;" and a note at the bottom of the page accidentally shows us that this is a part of Buchanan's text, and in page 46, we meet, "On this rule Buchanan remarks that it does not seem founded upon any satisfactory principle." In page 34, "Sometimes it may be requisite to have but few teeth in the pinion. In such cases, in the conducted whether wheel or pinion, Buchanan preferred staves to teeth;" and in page 36, "Every one considerably experienced in wheel-work knows that when a pinion comes to be considerably worn, the friction is greatly increased. Whereas no such thing happens to the trundle." In a note referring to this passage, it is said, "This is a mistake, as trundles in consequence of the surfaces of contact being small, become soon indented by pressure, and cease to turn round in their sockets;" but whether it is Mr. Buchanan who makes this mistake or Mr. Tredgold, we have no means of finding out. We are inclined, however, to believe it is the latter gentleman, as Buchanan is usually distinguished by name, and five lines further on from the text we have last quoted, we meet, "It appears, however, to Mr. Buchanan, that a wheel might be made which would combine the advantages of both the pinion and trundle."

We will not tire our readers with further quotations upon this head, we might extend them indefinitely, and it is no extenuation to say that the value of the information rendered is unaffected by the name of the preceptor. The confusion of persons might be excusable if it were essential to achieve some highly beneficial result, but only upon that untenable supposition. The perplexity it occasions to the reader is extremely disagreeable—it creates moreover a species of responsibility such as might be expected to arise from anonymous authorship that is by no means beneficial or expedient. That in re-editing a work relating to the practical arts or inductive sciences, it is right to make such additions and corrections as are answerable to the progress of improvement, we do not deny. But we deny to any editor the right to mingle his own commentaries or speculations with the original text in such a manner that they are indistinguishable from it. What would have been the fate of all ancient authors if their successive editors had assumed such a prerogative? If Mr. Buchanan undergo many such purifications, we fear he will be sublimated altogether. Where a work by the suppression of any palpable errors, and the addition of separate supplementary notices, is incapable of being rendered answerable to existing conditions, it is much better to reject the piece of antiquity altogether in favour of a new treatise. There is little

benefit in emulating the conservators of the ship of Colchis, who accomplished repair after repair until not a vestige remained of the original structure.

The definitions at the commencement of the volume, showing the precise acceptation of the terms wheel and pinion, trundle or wallower, teeth, cog, leaves and staves, are suitable enough, but we cannot see the utility of inserting in a work like the one before us, simple geometrical definitions, which may be found in several professional educational elementary works, besides about 20 pages filled with tables of square and cube roots. Surely the most moderate penetration might have discovered such insertions as these to be not merely superfluous, but to constitute a sort of "caput mortuum," highly detrimental to the quality of the work. Without conferring the smallest degree of benefit they create prolixity, induce confusion, and increase the expense of

the book, at the same time that they diminish its value. Having said thus much on the superfluous part of the work, we shall now proceed to direct the attention of our readers to the more valuable portions.

The following remarks (page 192) are judicious.

"Nor perhaps does the *simplicity* of a machine consist strictly in having *few moving parts*. If the parts of a machine be few, they are perhaps more easily taken in by the eye at one view, which may make them more easily comprehended by the mind, and in that sense be more simple. But in machinery the kind of simplicity at which we ought to aim has more regard to the *manner of action* than to the number of moving parts."

In page 95, we have a very useful table of the proportions of wheels in actual use, which we very willingly insert here.

TABLE OF PITCHES OF WHEELS IN ACTUAL USE IN MILLWORK.

Kind of Machine.	Horses' power.	Pitch in inches.	Breadth of teeth in inches.	Wheel.			Pinion.			Breadth proportionate to 10 horses power, and present velocity.	Present velocity per second, in feet.	Breadth in inches proportionate to 10 horses' power, at 3 feet per second, that is, reducing all the examples to the same denom.
				Teeth.	Revolutions per minute.	Diameter.	Teeth.	Revolutions per minute.	Diameter.

1 Has been 16 years at work. Teeth much worn.

2 Has been 16 years at work. This gearing was found rather too narrow for the strain, as it is wearing much faster than the rest of the wheels in the same mill.

3 The only defect in this gearing, which has been 16 years at work, is the want of breadth in the spur-wheel and pinion: they ought to have been 6 inches or more, as they will not last half so long as the bevel-wheels and pinions connected with them.

4 This is a better pitch for the power than Q.

5 This wheel has wooden teeth, and has been working for three years past.

6 Ditto.

7 This pitch has been found to be too fine.

EXPLANATION OF THE TABLE OF WHEELS IN ACTUAL USE IN MILLWORK.

The wheels are all reduced to what may be called one denomination.

First—By proportioning their breadths all to what they should be to have the same strength, if the resistances were equal to the work of a steam engine of ten horses' power.

Second—By supposing their pitch lines all brought to the same velocity of three feet per second, and proportioning their breadths accordingly. I have chosen this particular velocity of 3 feet per second, because it is the velocity very common for overshot water wheels.

Such cases as appear to have worn too rapidly, are marked, which may tend to discover the limit in point of breadth.

The Appendix A on the teeth of wheels by Professor Willis, is an important and well written paper, already known to the public, through the Reports of the Proceedings of the British Association, at the meeting held at Newcastle, and the Transactions of the Institution of Civil Engineers. The leading feature of this paper is the development of a method of making any pinion to work correctly with any wheel of the same pitch. The following extract explains the manner in which this is accomplished.

"From among the infinity of curves that may be offered the epicycloids and involutes have been universally preferred, on account of the facility with which they can be mechanically described, and perhaps because they admit of ready and independent demonstrations of their possessing the properties

required. But the practice has hitherto been confined to that class of epicycloids which work correctly with straight lines or circles. Teeth formed upon these principles possess this inconvenience, a wheel of a given pitch and number of teeth, say 40 if it be made to work correctly with a wheel of 50 teeth of the same pitch, will not work correctly with a wheel of 100 teeth of the same pitch. This is obvious, for the diameter of the describing circle by which the epicycloid is formed must be made equal to the radius of the pitch circle of the wheel with which the teeth are to work, and will therefore be twice as large in the second case as in the first.

In the old style of millwork in which the teeth of wheels always consisted of wooden cogs, this property offered no very serious impediment, although as we shall see it introduced some complication of method; but in the modern practice of making cast iron wheels the objection is a very serious one. A founder must make a new pattern of a wheel of 40 teeth for every combination that it may be required to make of this wheel with others, and the same for a wheel of any other number. Besides, it often happens in machinery that one wheel is required to drive two or more, whose number of teeth are different, and in this case the teeth cannot be correctly formed at all on the common principles; and again the perfection of machinery is impaired from the temptation to employ in one combination patterns which have been formed for another combination very nearly the same, for example, to make a wheel of 40 teeth that has been formed to work with one of 80, serve for a required combination of 40 with 85.

"It is essential therefore that the teeth of wheels should if possible be so formed as to allow a given wheel to work correctly with any other wheel of

the same pitch. Now it has long been known that involute teeth have this property, but the objections to these teeth on the score of the obliquity of their action have operated fatally against their introduction. I shall now therefore explain a method of imparting to epicycloidal teeth this property, and that without making them deviate very much from the general form which has been established by practice.

"To effect this it is merely necessary to employ a proposition well known and stated by almost every writer on the subject, namely, if there be two pitch circles touching each other, then an epicycloidal tooth formed by causing a given describing circle to roll on the exterior circumference of the one will work correctly with an interior epicycloid formed by causing the same describing circle to roll on the interior circumference of the other. This proposition having been already demonstrated, it is unnecessary for me to dwell upon it longer than to remark that our author (Buchanan) like all other writers on the subject, has passed from it to recommend for practice that particular case of it in which the describing circle being made equal in diameter to the radius of the pitch line, the interior epicycloid becomes a radial straight line, the inconveniences of which practice I have shown. The following corollary is I believe new, and constitutes the basis of the system I propose to explain.

"COROLLARY.—*If for a set of wheels of the same pitch a constant describing circle be taken and employed to trace those portions of the teeth which project beyond each pitch line, by rolling on the exterior circumference, and those which lie within it, by rolling on its interior circumference, than any two wheels of this set will work correctly together.*

"For in the first place it is well known, and can be shown from general principles, that the portion of tooth *within* the pitch line of a driving wheel works only with the portion that lies *beyond* the pitch line of its follower, and that its action is confined to the approach of the point of contact to the line of centres. After the point of contact of the teeth has passed that line, then the case is reversed, and the portion of the driving tooth which lies *beyond* the pitch line is in contact only with that part of its follower's tooth which lies within its pitch line. Now as a constant describing circle is used for the whole set, it is clear that the proposition will apply to any pair of wheels both before and after the teeth have passed the line of centres, for in each case we have an exterior epicycloid working with an interior epicycloid, and both have been drawn by the same describing circle, that is, by the constant circle of the set.

"To carry this scheme into practice it only remains to settle the proper diameter to be given to this constant describing circle, which may be done by considering the effect of this (its) diameter has upon the form of the tooth.

convex, and the base of the tooth lessen inwards, a form manifestly unpractical and useless. Hence the describing circle must not be greater than half the diameter of the pitch line.

"On the other hand if the diameter be too small the base of the tooth will spread inconveniently, and the curvature of the exterior epicycloids be injuriously increased, therefore on these grounds it should be made as large as it can, consistently with the limitation just stated, so that we finally obtain this rule for finding the diameter of the constant describing circle for a set of wheels.

"Make it equal to the radius of the least pitch circle of the set.

"And as pinions should never have less than 12 or 14 teeth, it would be well to establish one of these numbers as the least pitch circle.

"The proposition and corollary being perfectly general, will apply to racks which must be considered as (portions of) very large wheels, and also to annular or internal wheels. Accordingly, if the constant describing circle be employed in tracing their teeth, they will work correctly with any wheel of the set."

In page 149, Professor Willis describes a mode of drawing the teeth of wheels by means of compasses, that will work upon the preceding principles, and which, though not mathematically exact, is sufficiently so for practical purposes. We shall endeavour to describe this method without the aid of a diagram.

First describe the pitch circle—draw a diameter, and from the extremity of the diameter, with a radius of one-fourth of the diameter, set off an arc of the pitch circle. The point of intersection is the centre from which with the same radius, that part of the side of the

tooth extending beyond the pitch line is to be swept. To describe that portion of the tooth within the pitch line, draw a line through the extremity of the diameter, which makes an angle of 75° , with the line of centres, and fix upon a point in this line sufficiently low down to give a moderate concavity to the inner portion of the tooth when swept from that point as a centre. In the description of this method in page 149, the word "radius" is twice put for the word "diameter." There are various similar mistakes in other parts of the work.

The Appendix B on Roofs, by Mr. James Nasmyth, is a highly interesting paper, it explains the great utility of the lathe with the slide rest, and its importance to engineers.

The plates attached to the work are for the most part excellent, they exhibit several splendid specimens of machinery to be found in the manufactories of government and mechanical engineers of the first class. The typography is of the very first quality, and reflects much credit upon the parties concerned in the production. Notwithstanding the imperfections we have pointed out, the work will, we are confident, meet with an extensive sale. The subject of millwork is an important one, and there is no better treatise upon it than this edition of Buchanan's essays.

The Companion to the Almanac, 1842.

Our Christmas companion always affords us much pleasure, containing as it does a general view of the progress of many public works in this country. In the volume for the present year, we have some very excellent specimens of architecture, which clearly show that we moderns are not quite so far below the ancients as to be unworthy of notice. Liverpool before many years will have in St. George's Hall and the New Assize Courts, judiciously combined under one roof, and forming a splendid façade of the Corinthian order 420 feet in length, with a portico in the centre of 200 feet, one of the most splendid buildings in the country. The name of the talented architect is Mr. W. H. Lonsdale Elmes, the son of Professor Elmes, and it is with pleasure we learn that he is a very young member of the profession, for the design is one of promise. Sincerely do we hope that the Liverpool corporation will not frustrate him in carrying out his views; if allowed to carry out the design to the extent he proposes, Liverpool may then be justly proud of having a noble edifice.

By the same architect there is also another building, and in the same town, the Liverpool Collegiate Institution, which shows that Mr. Elmes is equally able in the Gothic as he is in the classic. The wood engraving, which is very badly got up, does not do the architect justice; we fortunately have seen the drawings and can speak of the building from them, and hope that we shall be able to illustrate our Journal with a view of the building, together with that of *St. George's Hall*. The other buildings illustrated in the book before us, are *Streatham Church*, architect, Mr. Wild; *St. Mary's Church, Southmark*, architect, Mr. B. Ferrey, who, as our author observes, has shown great discretion in not attempting too much, but endeavouring to produce effect by form rather than by decoration. *Trinity Chapel, Poplar*, architect, Mr. Hoskins; he has displayed considerable judgment in the construction of the roof, by which means a clerestory, is very ingeniously obtained, "containing five windows on each side over the galleries, and is formed within the general line of the roof in such a manner that it is not visible externally."—*Savings Bank, Bath*, architect, Mr. Alexander. "The structure is entirely faced with freestone, and is a tasteful piece of Italian *astylar* composition stamped by certain vigour and breadth.

We perceive that Oxford is making progress with its various architectural works.

Bartlett's Index Geologicus.

This is a diagram 3 ft. 6 in. by 2 ft. 9 in., containing a coloured section of all the geological strata, with complete catalogues of the fossil animal and vegetable remains, and of the series of minerals peculiar to each. Another column contains "statistics of the soils and indigenous flora," and the localities where the separate strata prevail, not only in Great Britain, but in other parts of the world, are particularly specified.

As a complete table of convenient reference, embracing in a highly condensed form and great body of information which had heretofore to be sought amid heaps of scattered materials throughout the works of many different authors. We strongly recommend the *Index Geologicus* to agriculturists, engineers, students in geology, and all others interested in this most important branch of natural history.

A Description and Historical Account of the Churches in the Division of Holland, in the County of Lincoln, with Illustrations. By Stephen Lewin.

The first number of this work contains views of Kirton Church and Algar-

kirk Church, and also a view under the Tower of Boston Church. To those who feel an interest in the many splendid Churches to be found in the rich diocese of Lincoln, we recommend a look at this work.

Tyler's Geology of England and Wales. By Samuel Hughes, C.E.

We have before us Part the first of a cheap Geological Atlas, which contains a map of the district round the metropolis, with a description. The editorship has been entrusted to Mr. Samuel Hughes, and the work appears to us for accuracy to be superior to any of its predecessors, while being at the same time a detailed map, it is much more available for all purposes.

The Railways of Great Britain and Ireland. By Francis Whishaw, C.E., &c. Additional Plates.

This is an interesting Addenda to Mr. Whishaw's large work, which we noticed a few months since; the first plate shows the length, summit, and general levels of the main English lines above the Trinity high water datum—the next plate contains drawings of six different wheels in use upon railways, the third and last plate is a curious diagram exhibiting at one view the prices of railway shares on the London Stock Exchange, from the first commencement of the railway to the end of October 1840.

An Essay on Architectural Practice. By T. L. Walker, Arch. F.R.S.B.A.

This essay is the first section on the construction of general working drawings; it contains the contract drawings, specification and bill of quantities of one of the New Churches built under the author's superintendence, in the vicinity of Bethnal Green. The drawings are shown with great clearness, with their dimensions correctly marked thereon, and the specification is well drawn, detailing with great perspicuity the nature of the work to be executed. The student will find this essay a good example for study, to whom we strongly recommend it.

CHUBB'S PATENT WELL-SAFE.

MANY parties purchasing fire-proof safes, would gladly avail themselves of the further security, by depositing them in a well, or pit,

under ground; but they have been unable to do so, in consequence of the space required, and cumbrous nature of the apparatus hitherto employed in raising and lowering the safe: Mr. Chubb has provided against this inconvenience, by his newly-invented apparatus, as shown in the annexed engraving.

The Safe, which stands in its appropriate place in the counting-house, may be lowered to any depth, by means of machinery concealed in a protecting encasement under the floor; the movement is effected by means of mechanical action, which any individual can perform, and the Safe is lowered or raised, in an inconsiderable time, without noise, or the possibility of danger to any one. But an additional safety, of special importance, that of concealment to the whole, is provided by the iron fire-proof door, level with the floor of the apartment, and secured by a strong detector lock, with bolts throwing each way. It will be at once obvious, that this mode of securing the Safe under ground, will afford effectual and entire security against the most extraordinary ravages of fire, or the danger arising from the occasional violence of riotous attacks for the purposes of depredation.

MISCELLANEA.

Knightsbridge Improvements.—The Cannen Brewery and the Fox and Bull public-house have been taken down to make room for a splendid architectural entrance into Hyde-park, to be called the "Albert Entrance." The houses on either side along the park, extending to the Horse Barracks, belong to the Dean and Chapter of Westminster. In former times, prior to the dissolution of the monasteries by Henry VIII., where Lowndes-square stands was a coppice which supplied the Abbot and convent of Westminster with fuel; and even to this day the Westminster scholars are permitted to burn large logs of beechwood in their dormitory, which are now supplied by the College porter. Westminster Abbey has been, from a very distant period, supplied with spring water from an aqueduct at Bayswater, communicating to a very pretty Gothic conduit-house erected by the Dean and Chapter at the lower end of the Serpentine in Hyde-park. The pipes are leaden, and although they have been under ground for many centuries are yet perfectly sound. They pass through the Green-park and the end of the ornamental water in St. James's-park, at the spot where a stone is erected, and through Queens-square, to the Abbey.

The Improvements in Threadneedle Street.—The building which is now in the course of erection on the site of the old French Protestant church, in Threadneedle-street, has, for some time past, attracted the attention of all passers-by, although it is not yet completed, nor likely to be so for some months to come, on account of the nature of the ornamental designs, which require the strictest attention on the part of the artists employed. The basso-relievo is intended to occupy the whole extent of the front of the building. The skill and taste displayed in the erection of this new edifice are well worthy of the attention of all lovers of the fine arts, who will do well to take an opportunity of visiting it. The proprietor, who bought the ground from the city authorities, after it had been determined to pull down the old French church, very handsomely conceded to the latter, without receiving any consideration whatever, 10 feet of the entire frontage, for the express purpose of giving that additional width to the street, the narrowness of which has always been found so excessively inconvenient. This disinterested conduct on the part of an individual should, and doubtless will, call for a corresponding feeling on the part of the city authorities, who, with this example before them, are, as it were, bound to proceed with the improvements, and to continue the additional width throughout the whole extent of Threadneedle-street. If the whole of the northern side of the street, from Old Broad-street to the Old South Sea House, were taken down, and thrown back a space of ten feet, in order to correspond with the building in question, a noble street would be formed, well calculated to make a fine approach to the new Royal Exchange. In fact, we know of no part of London where a greater display of elegant architecture will be found, than that which will be exhibited in the course of next year in the immediate vicinity of Cornhill and Old Broad-street, &c.

Sunderland.—Last month the New Church, recently erected at Deptford, was consecrated. It is built in the early English style of architecture, and is large and commodious, being 110 feet 9 inches long by 54 feet broad. There are three galleries in the church, which is altogether capable of seating about twelve hundred persons, nine hundred of which are free sittings. The architect is Mr. Thomas Moore, of Sunderland.

Professorship of Architecture, University College.—The movement as to architectural professorships continues. Mr. Donaldson has been appointed to the chair in University College, London, a choice which will be of advantage to the college and profession.

"The Thames" Steam Ship.—This splendid vessel, built for the West India Mail Steam Packet Company, made a trial trip on 14th ult. She was built by Mr. Pitcher, of Northfleet, and is a fine specimen of naval architecture for standing sea service, and at the same time having every convenience for passengers. For making the passengers comfortable every contrivance that could be introduced has been thought of, while the saloons have been fitted up with great taste and beautifully decorated. The engines were constructed by Messrs. Maudslays and Field, and are of 400 horse power, being made from the same models as the Great Western, which have done so much credit to the talented engineers. The speed attained at the trial mile in Long Reach was about twelve miles through the water.

The King of Prussia has given orders for the restoration of the palace at Coblenz, and it is supposed that the Rhenish States will meet there and at Dusseldorf alternately. The King has ordered 50,000 dollars for the building of the cathedral at Cologne, and has promised from the treasury 30,000 dollars yearly, in addition to sums for the purchasing up the houses at present surrounding that magnificent building.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 25TH NOVEMBER, TO 23RD DECEMBER, 1841.

Six Months allowed for Enrolment.

ROBERT WILSON, of Sowerby Bridge, Halifax, currier and tanner, for "improvements in the manufacture of leather."—Dec. 2.

WILLIAM IRVING, of Princes-street, Rotherhithe, gentleman, for "improvements in the manufacture of bricks and tiles."—Dec. 7.

JAMES COLMAN, of Stoke Holy Cross, Norfolk, starch manufacturer, for "improvements in the manufacture of starch."—Dec. 9.

WILLIAM HENRY FOX TALBOT, of Lacock Abbey, Wilts, Esq., for "improvements in coating or covering metals with other metals, and in colouring metallic surfaces."—Dec. 9.

JOHN HALL, of Breezes Hill, Ratcliff Highway, sugar refiner, for "improvements in the construction of boilers for generating steam, and in the application of steam to mechanical power."—Dec. 9.

ARCHIBALD TEMPLETON, of Lancaster, silk spinner, for "a new or improved method of preparing for spinning silk and other fibrous substances."—Dec. 9.

JONATHAN GUY DASHWOOD, of Ryde, Isle of Wight, plumber, for "improvements in the construction of cocks and taps."—Dec. 9.

MOSES POOLE, of Lincoln's Inn, gentleman, for "improvements in the construction of masts for ships and vessels, and in applying the shrouds."—Dec. 9. (A communication.)

JOSIAH TAYLOR, of Birmingham, brass founder, for "improvements in the construction of lamps."—Dec. 9.

ROBERT HENDERSON, of Birmingham, china dealer and glass stainer, for "certain improvements in apparatus for heating and lighting apartments, and for other like purposes."—Dec. 9.

HENRY WILKINSON, of Pall Mall, gun maker, for "improvements in machinery to be used in constructing buildings, and in raising and lowering weights and materials."—Dec. 9. (A communication.)

JOHN EDWARDS, of Shoreditch, warehouseman, for "improvements in giving signals on railways."—Dec. 11.

WILLIAM GEORGE HENRY TAUNTON, of Liverpool, engineer, for "improvements in machinery for raising weights."—Dec. 11.

WILLIAM WESTLEY RICHARDS, of Birmingham, gunmaker, for "improvements in the construction of gun and pistol locks and primers for the discharge of fire arms."—Dec. 14.

WILLIAM EDWARD NEWTON, of Chancery-lane, civil engineer, for "improvements in printing and delineating patterns, and printed cloths for floor cloths, covers, and other uses."—Dec. 14. (A communication.)

FRANCIS MAB, of 81, Eaton-square, Esq., for "certain improvements in the construction of ships or other vessels, and the method of propelling them."—Dec. 16. (A communication.)

WILLIAM NELSON, builder, DAVID LYON, builder, and PETER M'ONIE, engineer, all of Glasgow, for "improvements in cutting, dressing, preparing, and polishing stones, marble, and other substances, and also in forming flat or rounded mouldings, and other figures thereon."—Dec. 16.

CHARLES EDWARD AUSTIN, of Fulham, engineer, for "an apparatus for what is commonly called 'changing the line,' on railways."—Dec. 16.

JAMES STEWART, of Onaburg-street, Regent's park, pianoforte maker, for "an improvement in the construction of castors."—Dec. 16.

WILLIAM PROWETT, of Northamptonshire, victualler, for "improvements in giving signals on railways."—Dec. 16.

HENRY BOOTH, of Liverpool Esq., for "improvements in the method of propelling vessels through water."—Dec. 16.

JOHN NORTON, of the Junior United Service Club, Regent-street, Esq., for "improvements in sheathing ships and other vessels."—Dec. 16.

ANTOINE MERTENS, of the London Coffee-house, publisher, for "improvements in the manufacture of plaited fabrics."—Dec. 16.

WILLIAM CHURCH, of Birmingham, civil engineer, and JONATHAN HALL, of the same place, manufacturer, for "improvements in the mode of manufacturing metallic tubes, and in the mode of joining them, or other tubes or pieces, for various useful purposes."—Dec. 16.

THOMAS STARKER, of Birmingham, copper cap manufacturer, for "improvements in percussion caps for discharging fire-arms."—Dec. 16.

JOHN AMERICUS FANSHAW, of Hatfield-street, Christ Church, gentleman, for "an improved manufacture of waterproof fabric, applicable to the purposes of covering and packing bodies, buildings, and goods, exposed to water and damp."—Dec. 16.

WILLIAM BUCKWELL, of Trinity-street, Borough, civil engineer, for "improvements in scaffolding or frame-work for building purposes."—Dec. 16.

CHARLES LOOSEY, of Half-moon-street, Piccadilly, civil engineer, for "improvements in steam-engines, and which improvements are also applicable in raising or forcing water and propelling vessels."—Dec. 16.

JOHN BOULD, of Overden, Halifax, cotton spinner, for "improvements in condensing steam-engines."—Dec. 16.

ANTOINE JEAN FRANCOIS CLAUDET, of High Holborn, glass merchant, for "improvements in the process or means of, and apparatus for, obtaining images or representations of nature or art."—Dec. 18.

HENRY HOUGH WATSON, of Bolton-le-Moors, Lancaster, consulting chemist, for "improvements in dressing, stiffening, and finishing cotton, and other fibrous substances, and textile and other fabrics, part or parts of which improvements are applicable to the manufacture of paper, and also to some of the processes or operations connected with printing calicoes and other goods."—Dec. 21.

WILLIAM EDWARD NEWTON, of the Office for Patents, 66, Chancery-lane, civil engineer, for "improvements in lamps and burners, and in the means of supplying air and heat thereto, for the support of combustion."—Dec. 21. (A communication.)

WILLIAM NEWTON, of the Office for Patents, 66, Chancery-lane, civil engineer, for "improvements in cleansing wool, and facilitating the operation of dyeing; and also in washing and bleaching cotton yarns or fabrics."—Dec. 21. (A communication.)

JOHN TOPHAM, of Whitecross-street, engineer, for "improvements in engines, machines, apparatus, or means for extinguishing or stopping the progress of fire in any room or part of different buildings, which may have become ignited, such as noblemen or gentlemen's mansions, houses, factories, store and warehouses, and consequently preserving them from destruction, and preventing the loss of life."—Dec. 21.

GEORGE PALMER HENRY, of Peckham, chemist, for "improvements in apparatus, to be applied to the glass chimneys of gas burners."—Dec. 21.

JOHN COX, of Gougie Mills, Edinburgh, tanner and glue-maker, for "improved processes of tanning."—Dec. 21.

JOHN OLIVER YORK, of Upper Coleshill-street, Eaton-square, engineer, for "improvements in the construction of railway axes and wheels."—Dec. 21.

WILLIAM CARRON, of Birmingham, lathe-maker, for "improvements in the construction of clogs and pattens."—Dec. 21.

WILLIAM HENRY SMITH, of Finsbury Chambers, Bloomfield-street, civil engineer, for "improvements in the construction and manufacture of connectors or fastenings, applicable to garments, and other uses."—Dec. 21.

ADOLPHE FOURMENT, of Museum-street, engineer, for "improvements in castors for cabinet furniture, and other purposes."—Dec. 21.

THOMAS WRIGHT, of Church-lane, Chelsea, Lieutenant in the Royal Navy, and Alexander Bain, of Percival-street, Clerkenwell, mechanist, for "improvements in applying electricity to control railway engines and carriages, to mark time, to give signals, and print intelligence at distant places."—Dec. 21.

HENRY ALPHONSE BONNEVILLE BOUVIRON, of Trevor-square, merchant, for "improvements in axletrees."—Dec. 21. (A communication.)

WILLIAM BURGE, of Bristol, sign painter, for "improvements in propelling vessels."—Dec. 21.

WILLIAM CARR THORNTON, of Cleckheaton, machine-maker, for "improvements in machinery or apparatus for making cards for carding cotton and other fibrous substances."—Dec. 21.

JOHN WATSON, of Chorley, Lancaster, Gent., for "improvements in the construction of filters, used in the manufacture of sugar."—Dec. 23.

WILLIAM BAILLIEN, of Gloucester-street, Queen-square, Bloomsbury, musician, for "improvements in apparatus to expand the human chest."—Dec. 23.

TO CORRESPONDENTS.

On account of the Index, &c., being more than usually heavy, this month, we have been obliged to postpone some valuable communications, particularly one on Egyptian architecture, and also the important evidence respecting the explosion of a boiler at Manchester.

Communications from "Seyton" and others must stand over. "A Civil Engineer." Several designs have been submitted to the Corporation of the City of London, for the improvement of Holborn Hill.

"B." must, upon consideration, see that we cannot insert his communication, for our Journal might be filled with similar announcements.

All controversial articles must be subject to our cutting them as short as possible, for we do not wish to extend discussions unnecessarily; too often they contain a great deal of acrimony.

"A." His communication wants revising; will he do us the favour to say where it can be sent for correction.

Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," No. 11, Parliament Street, Westminster.

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, III, and IV, may be had, bound in cloth, price £1 each Volume.

THE NATIONAL SCOTCH CHURCH,

CROWN COURT, BOW STREET.

THE taste and feeling which a professor of architecture brings to the practice of his art, may be evinced not alone by his style of erecting new buildings, but in a scarcely inferior degree by a judicious alteration of old ones, and though it is not our practice to notice these latter, we think ourselves justified in departing from it, in the instance of the Scotch National Church exhibited in the annexed wood engraving, which has lately been remodelled by Mr. Robert Wallace.

This structure, being under every disadvantage of situation, is likely to be seen by few; having its "locus" in a retired spot called "Crown Court," which forms a connecting link or thoroughfare between Bow Street, Covent Garden, and Little Russell Street.

Though far from being an erection of yesterday, the claims of the original building do not reach to *antiquity*; it would appear in fact, to have been erected something like a century ago, when Presbyterianism and plainness were held to be synonymous, and when the "Scots' Kirk," notwithstanding its *national* character, and the legislative sanctions under which it exists in the sister kingdom, ranked only in the public mind as a variety of the Methodist or dissenting chapel. The conventicle or sectarian character was, up to September last, broadly impressed upon it. Its plain brick front, extending to 60 feet, was pierced in the upper part by a range of 7 semi-circular headed sash windows, between which and the lower openings, consisting of 5 windows with outside shutters, and 2 wood door pieces, with fan-lights; over, was a considerable space (10 ft.) of plain brick-work, occasioned by the steep rise of the gallery within. The projection of the porches was about 3½ feet, leaving an unoccupied space or area intermediately, and at the ends, enclosed by an iron railing.

With these elements for the architect to deal with, and with the desiderata impressed upon him, 1st, of imparting to the building an ecclesiastical character, and 2nd, of obtaining an external access to the galleries, without injury to the existing lights, he has produced the façade represented in our engraving, the round-headed windows which prevailed throughout the upper story of the building, having suggested the Norman style. It may help to explain the diagram to observe, that the large open arch in the centre of the front gives access to the new external stone stairs, which ascend to the right and left (passing over the heads of the two ground floor entrances) between the pierced screen and the main wall: that the two higher features which break and give variety to the line of front, result from the necessity of forming a headway to the staircases, continued up in them, and entering to the highest level of the gallery, below the sills of the two extreme windows, which receive their light from the front and lateral openings in the towers which mask them in the view. It may further be observed that all the apertures in the new front are open or unglazed (except the two lowest ones in the turrets) in order not to impede the light to the old ones in the main fabric, all of which retain their old forms and positions.

The principal alteration in the interior, consisting of a large semi-circular arch behind the pulpit, embracing in its intrados two smaller ones glazed heraldically, is in correspondence with the exterior, while the pulpit, gallery front, and fittings, it was thought justifiable to render into the Tudor taste.

ON REVERSING ENGINES.

Fig. 1.—Section of Smoke-box.

Fig. 2.—Transverse View of Smoke-box.

SIR—As we have seen in your pages a plan of reversing engines, signed G. Coe, civil engineer, which is in principle similar to ours, of which we have been constructing a small sectional model for a locomotive engine, we take the liberty of sending you a small sketch of it, with the request, if you think it worth your attention, to give a place in your Journal. Figs. 1 and 2, show only those parts of a locomotive engine, which are wanted for the explanation of our new improvement.

A is the steam-pipe which carries the steam into a cylinder B, fixed in the smoke-box. In the cylinder B, of about 8 inches inside diameter, move 2 pistons C and D, connected by a pipe E, which can be cast between the pistons, as the distance between C and D must be always the same. The piston rod is connected with the pistons by means of a boss fixed to D, by 3 stays, and is guided in the stuffing boxes G and H. On the top of the cylinder B, is the exhausting pipe F, on its sides are short pipes K K' and L L', which have a section of 5 in. by 1½ in., where they enter the cylinder, and a round section on the other end.

The steam cylinders M M', have instead of valve boxes, cylinders N and N', with pistons 1 and 2, similar to those in the cylinder B, and those cylinders N and N' are connected with B by means of the pipes K K' and L L'. The pistons 1 and 2 will act exactly like a common valve in respect to shutting and opening the steam passages 3 and 4 of the steam cylinders M M', as they are moved by a common eccentric, (keyed to the crank shaft) by means of the levers R S and Q F.

As we have given now all the explanation of the different parts shown in the sketch, we will next explain how we start, reverse, and stop the engine, without disengaging the spindles of the pistons 1 and 2, from their eccentric rings.

Suppose the engine is to start in the direction shown by the arrow the stand of the pistons C D in the cylinder B, would be as the sketch shows it. The steam will pass through the pipe E, go through the pipes L L', down to the cylinders N N', round the pipe 5 through the passage 3, into the steam cylinder, and drive the piston in the direction of the arrow; the steam on the other side of the piston will pass through the passage to the pipe 5, up through K K', and enter the cylinder B, from where it can freely exhaust by the pipe F. If it is wanted to stop the engine, the rod O is moved, by means of a lever or a handle with a screw above the fire-box, towards B, till the pistons cover the pipes L L', in that case the pipes K and K' will still allow the steam to pass round the pipe E, into the pipe F, and as there is not any more steam entering the steam cylinders, the engine will stop. It is clearly to be seen that the engineer has it quite in his power to change the areas of the pipes L L', by moving the pistons backwards or forwards, without altering the areas of the pipes K K'.

To show now the reversing of the engine, the rod O is moved in the direction towards B, so that the piston D' opens the communication between the pipes L L' and the exhausting pipe F; and by this the pipes K K' will come in communication with the steam pipe A. The steam will pass through K K', the pipe 5, and the passage from 2 into the steam cylinder, and force the piston 6 in the reverse way; the steam from the other side of the piston passes through the passage 3, round the pipe 5, up through the pipes L L', and out in the exhausting pipe F.

After this explanation it will be seen that by moving our apparatus for moving the engine, a regulator is not required.

We have now to describe how to get lead.

There is only one broad eccentric keyed to the crank shaft, with two eccentric rings, each having a circular slot, which is shown in fig. 3.

Suppose now the pin of the lever S (moving the piston rod *m*, by means of the lever R on the shaft P), stands in the point 2, then the engine would have no lead, but as the friction between the eccentric and its ring, wants to take the ring with the eccentric, it will go round with it till the pin of the lever S has come in the point 1, when it will have the position wanted for the lead. When the engine is reversed the eccentric ring will turn with the eccentric till the pin of the lever S has arrived in the point 3, which will then give the position required for the lead of the reverse of the engine. The eccentric line 2 of the circular slot of the other eccentric ring for the adjoining machine, stands in an angle of 90 degrees to the centre line of the circular slot of the other eccentric ring, through which the lever T and Q, works the piston rod of the adjoining machine.

The levers R and S, and T and Q, can work on a fixed shaft P, by means of loose bushes, or the shaft P has to be divided in two, and then the levers can be keyed or forged on the shaft.

We are, Sir,

Your obedient servants,

H. AND P.

15, Bedford Street,

Chorlton-upon-Shedlock, Manchester.

BRAITHWAITE'S APPARATUS FOR DISCONNECTING THE PADDLE WHEEL OF STEAM VESSELS FROM THE ENGINE.

Fig. 1.—Side view.

Fig. 2.—Section.

In our last number we gave a description of an apparatus for connecting and disconnecting the paddle wheels of marine engines. We have now another apparatus to describe, which appears equally as effective, and very simple in its action. It has lately been tried at Woolwich, on board H. M. steam vessel "Kite," and found to answer the purposes intended; it is the invention of Messrs. Braithwaite, Milner & Co., of the New Road. The annexed drawings and description fully explain its action.

- A, Paddle wheel shaft.
- B, Crank pin.
- C, Cast iron disc keyed to shaft.
- D, Brass friction band fixed by screws to the external wrought iron rim G.
- E, Brass friction break.
- F, Iron key wedge, head, 4" x 1½".
- G, External rim, 2½" x 6" of cast iron keyed to crank pin.

For the purpose of disconnecting the crank, it is only necessary to drive out the key, which immediately relieves the brass break E from pressing against the cast iron disc, and allows either the external rim and the crank or the internal disc and shaft to revolve independently of each other.

For the purpose of connecting the apparatus, it is only requisite to drive in the keyed wedge, which forces the brass break E against the iron disc.

ON THE PROPORTIONS OF STRAPS FOR DRIVING MACHINERY.

SIR—Although the subject of the present communication may, to some of your readers, appear of a nature too frivolous, or not altogether adapted to the character of your journal, it is still a subject of the most frequent occurrence to the practical mechanic, and probably that which receives the least of his attention. However, I cannot recollect ever seeing in print any rule or proportion relative to the breadths of straps for driving. Probably this is owing to the great variety of circumstances to which straps are subject, and which differ more or less in almost every case; such for instance as horizontal, vertical, long, short, open, and crossed straps, the pliability of the leather, and so on. A horizontal strap is better than a short one, and a long horizontal strap will always perform its work with much

greater ease than a short one. A crossed strap, whether horizontal or vertical, is known to be more powerful than an open one, &c. But I will not pretend to give any rule for determining the power of a strap; the object of this communication is, to direct your attention to a combination of straps.

In a combination, that is, a number of straps one working another over drums and pulleys for multiplying the number of revolutions, it is very common for one or two of the straps to be constantly breaking or giving way, while the others work for months and months without requiring the least repair. The straps which most frequently get out of repair are generally those which travel at the greatest velocity, and it is to the rapidity of their motion that their frequent breaking, &c., is generally attributed: but I am inclined to think that this is not the real cause, in proof of which I will here give an instance of a very recent occurrence that came under my notice.

The annexed sketch shows the arrangement of the drums, straps, &c. The strap A was $4\frac{1}{2}$ inches broad, B, on account of its greater velocity, was at first made only 2 inches broad, but when it came to be tried the consequence was, its not being able to drive the machine without being so tight as to be constantly breaking, wherefore it was replaced by one an inch broader; this too was far from performing its work in a satisfactory manner. Although this strap was two-thirds as broad as the driving strap A, and travelled at a velocity three times as great, it was still found necessary to increase its breadth to 4 inches, and even then it required considerably more attention to prevent it from slipping than A.

The peculiarity of this circumstance induced me to give the matter a little consideration. The proportions of the pulleys were such as caused the velocity of B to be three times as great as that of A; this informed me that a given force applied to C would only produce one-third of its effect at D, and consequently, that the strap A demanded a breadth three times that of B, which I knew not to be the case in practice. A second thought reminded me of having occasionally observed the pulley E perfectly still, at the same time the strap B was carried round with the drum D at full velocity. This pointed my attention towards the very small amount of strap-surface acting upon E, compared with that acting upon C. At this moment it occurred to my mind, that the breadth for the strap B, necessary to communicate power to E proportional to that possessed by C, depended *not* upon the breadth of the strap A, but upon the *amount of its surface acting upon the circumference of C*.

I next proceeded to ascertain the length of strap a C a, which being multiplied by $4\frac{1}{2}$ inches (its breadth), gave 121.5 inches, the amount of its surface in contact with the pulley. Then as 1 (the velocity of A) : 121.5 :: 3 (the velocity of B) : 40.5 the amount of surface required to act upon E. Now $40.5 \div 8$ inches (length of strap acting at c E c) = 5. &c. I was then clearly convinced that the strap B, which had been increased from 2 to 4 inches broad, demanded a breadth of 5 inches to render it capable of producing an effect upon E proportional to that produced by A upon C.

In some instances straps thus proportionate may require to be of an unsightly breadth, but then is it not evident that in such cases, the first determined strap is broader than necessary? However, I am of opinion that in many cases of ordinary occurrence, the broad straps are more suitable to occupy the situations of the narrow ones, and *vice versa*. In conclusion, I trust, supposing what I have here said to be successful in conveying my meaning, that those whose curiosity may lead them to give the subject a little consideration, will with myself agree, that the breadths of straps in a combination *ought not*, as cog wheels, to be proportionate to their velocity; but that their breadths are dependent on the *amount of their surface acting upon the smaller pulleys*, in proportion inversely to their velocities.

I am, Sir, in every respect,

Your humble servant,
VESPER.

Leeds, January 11, 1842.

ON ARCHITECTURAL PRECEDENT. (TO H. S.)

THE remarks on architectural precedent by H. S. were particularly pertinent, and would have been perfectly clear, had the concluding paragraph been omitted; but the opinion there expressed is very far from self-evident, and will certainly require further explanation. Our endeavours should always be to surpass our predecessors in the scale of excellence, not by undervaluing them, while we remain stationary, to prove that they are inferior to ourselves; and something more is surely required than a neat antithesis, to depreciate the character of a people whose works, whether of art or literature, have been the delight of men of taste for more than 2,000 years.

The system of classical education 50 years ago might well keep up the prejudice against Gothic architecture; but that is now in a great measure done away, and the evil of architectural precedents is as great as ever, and influences Gothic quite as much as Grecian. There must therefore be some other cause for the evil than that cited by H. S.

Every ancient building is useful in the education of an architect, as exhibiting what has been produced by the genius of our predecessors, and what method of proceeding circumstances have induced them to adopt. Grecian architecture affords specimens of carefully-studied and accurately-beautiful proportions; the grandeur produced by simplicity of plan and construction, and the careful treatment of detail:

and the excellence of their sculpture, which no one has ever questioned, indicating a superiority in one branch of art, demands from us a more careful examination of their architecture than a superficial view might first appear to render necessary. Roman exhibits the effect of magnitude, combined with greater multiplicity of parts, increased complexity of plan, and skill in construction. In Gothic we see a rather less complicated plan—the extreme of constructive skill—and a grandeur of effect united with a richness and delicacy of detail combining in this respect the excellencies of the Greeks and Romans. In the same manner something may be learned from every style, Egyptian, Indian, Mahometan, &c. From these studies the architect discovers the principles of taste, and the power of criticising not only the works of others, but what is more difficult, his own. At the same time that he is profiting by their experience he must exercise his invention by constant practise, and he need not fear the greatest exuberance of fancy, if restrained by good taste, being only dangerous where it obtains the mastery over judgment. Beyond this, as materials, which are the common property of every body to cut and remodel, or copy with such variations only as indicate that while we assume the manner we entirely disregard the spirit, they are absolutely worse than useless. This, however, is the abuse, and should not discourage a judicious use of them.

J. L.

DITTO TO H. S.

SIR—Of the "Hints on Architectural Criticism," I say nothing, they being to me as mysterious as Lord Burleigh's shake of his head, and no doubt equally significant, although few, I suspect, can comprehend the writer's meaning and "attitude." But the paper of your Derby correspondent, H. S., has afforded me very great satisfaction; for, as far as it goes, it is exceedingly sensible, and very much to the purpose. Without at all undervaluing the merits of classical architecture, without depreciating it in itself, it is time for us to get rid of that extravagant pedantry and that bigoted reverence for it, which are for the most part no better than cant. And it is owing to this cant, by the bye, that the belief in the vast superiority of the ancient orders is "so universal," such belief being adopted ready-made, without inquiry or investigation, and consisting of little more than "raptures learnt by rote."

Were it found that ancient architecture accommodates itself perfectly to, and is all-sufficient for, our purposes at the present day, there might be something like reason in deprecating any departure from its precedents. Such, however, is by no means the case; on the contrary, it inevitably becomes more or less changed in its character—in some instances, has been most of all metamorphosed by those who affect the greatest veneration for it. It is, therefore, quite absurd to lay so much stress as is done on the mere copying by routine a few details, when, after all, the aggregate effect—the *ensemble*—must be totally unlike that of the structures from which some of the individual parts are mechanically borrowed. Surely, if an architect does not scruple to *innovate* so largely as to introduce windows within porticos, or between Grecian columns,—if he does not consider features of that kind as at all foreign to classical architecture, or as derogatory from its so greatly-extolled simplicity and purity,—it is most contemptible affectation, or something still worse, to insist upon, and even make a merit of, strictly copying the mere conventional embellishments of the order itself that happens to be employed, and which is for the most part dragged in, sometimes with, but oftener without, any appearance of utility or propriety. In fact, such pretended veneration for the models of antiquity is seldom little better than a plausible excuse for not bestowing any study on, or attempting any originality in regard to the character of an *order*—even such modification as would render it more of a piece with the rest; whereas, as now treated, the classical order chiefly serves to show how very unclassical the structure itself is. In fact, it is only cant on the one hand, and custom on the other, which reconcile us to the practice of *hashing-up* Grecian architecture after the fashion we do, sticking the columns borrowed from some antique example before a building full of windows, the latter being, perhaps, only so many holes in the wall. Except that custom is not in its favour, it would not be a whit more preposterous to introduce pointed windows of rich design into an otherwise perfectly plain front, and pass it off as a specimen of the Gothic style.

Under the plausible pretext of reverential respect for the precedents of antiquity, its ultra admirers would limit us at the present day to "servile copyism," although necessarily imperfect in itself; and strenuously set their faces against, and deride, even beforehand, any attempt to originate novelty in architectural detail. Most triumphantly do they refer to previous failures, although the last in fact prove nothing, except that those who made the unlucky experiments were in every respect unfitted for the task they assumed, since they plainly showed themselves to have no principle of taste in common with that of the ancients. To enlarge upon the present system of the orders requires a taste *well-nourished* by previous study of them, and not, as seems to be assumed, mere fanciful caprice and whim. Either architecture is not a fine art at all, or it admits of originality and invention—guided, be it understood, by judgment and good taste. It most assuredly does not follow, that every one is capable of displaying those qualities; yet, though it may be advisable for the many to adhere with exactness to established precedents, as being by far their

safer course, that is no reason whatever why all without distinction should be interdicted from exercising their originality; nor is it in accordance with common sense, that no liberty of invention should be allowed, merely because, in aiming at originality, some have run into the most puerile and tasteless extravagances. Emancipating himself from precedent, Emlyn invented "a new order," and one so preposterously absurd and tasteless, that it has deservedly covered his name with ridicule. What then? Schinkel, also, emancipating himself from precedent, produced several novel designs for capitals, exhibiting the most refined and exquisite taste. "But," exclaim the bigots, "we do not want new capitals or new orders; the old ones are quite sufficient for our purpose;" which is but a very sorry kind of argument in matters of art. They assure us, moreover, that it is impossible for us to improve upon the ancient orders, or to produce anything new that shall rival them. Yet this is but silly and evasive reasoning; they might as well tell us that St. Paul's was intended as an improvement upon the Parthenon, and is consequently a decided failure. If originality can produce what is good in itself, it is not to be condemned because it may happen to fall short of foregone excellence.

DITTO.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XXXIV.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. WE have had both Rejected Addresses, and Rejected Articles, and why not Rejected Designs? Were some productions of the latter kind published, they would assuredly be of service, either one way or other; either by reconciling us to those which have been preferred to them, and carried into execution, or by showing what sort of taste and judgment it is that generally decides in such matters. That the best design offered is invariably the one selected, is what people in general may suppose, it being according to common sense that such should be the case; but it is what no one who is in the slightest degree conversant with such transactions will for a moment believe. We have seen rejected designs, which have been in every respect greatly superior to the one that has been adopted, and which could have been executed for the same sum, if not even for less. Greatly, therefore, is it to be desired, that some "*contrasts*" of the kind should be published, in order to let people see how much better things they might have had than what they have now got, and what kind of wiseacres they are whom they suffer to choose for them. In one point of view, such contrasts would be amusing enough, yet in another they would be sadly mortifying; still, the very mortification itself might have salutary consequences, by teaching greater caution for the future, and making Competition Committees more careful and scrupulous, from the dread of ultimately committing themselves.

II. Mr. Thomas Roscoe shows himself to be either the most mendacious or most ignorant of writers, when he assures us that Burgos cathedral bears a striking resemblance to that of York. "Its steeples," he says, "terminating in spires, and vast square towers with eight pinnacles, correspond *exactly* with those of the English church; and to complete the likeness, we have a lower octagonal building with eight pyramidal turrets, terminating in needles, piercing a star-like ornament, which the reader will at once recognize as the counterpart of the Chapter-house at York." Mr. Roscoe's readers may, perhaps, be capable of swallowing anything; yet, doubtless, some even of them must have been startled—at least strangely puzzled and perplexed—

on comparing that description with the accompanying views by Roberts, to which it was intended as explanatory; for if they know anything at all of the English cathedral, they must have wondered how any one can trace any sort of resemblance between the two edifices, or between their respective Chapter-houses. Whether Roscoe had unfortunately got hold of a print of York Cathedral at the time, supposing it to be the representation of that of Burgos, I know not; but nothing short of some strange mistake of the kind can account for his blundering remarks. It is true, both Burgos and York have two western towers, yet so also has St. Paul's; and therefore, at least as far as the façade is concerned, he might as well have compared it with that of the last-mentioned structure. The exact similarity which Roscoe is lucky enough to be able to perceive between Burgos and York, is *exactly* like that which exists between a dog and a cat, both of them being animals with four legs and a tail; and no doubt he would have pointed out that remarkable coincidence, had he been writing a book of natural history. The west front of Burgos has two very rich spires of open-work tracery, and is otherwise of peculiar design, while York has nothing whatever of the kind. The centre compartment of the first shows no gable, but terminates in a horizontal deep parapet of open arches, &c., with a canopied niche in its centre: the other, on the contrary, has an embattled gable or pediment, covered with tracery. At Burgos, this portion of the front is divided into two tiers of windows, viz. a large rose window below, and two arched ones above it; whereas, at York it has a single large window, gabled and embattled, and remarkable for the pattern of its tracery. In fact, there is no sort of resemblance between the two structures; since whatever they have in common constitutes also a decided difference. It may perhaps be some little excuse for Roscoe, that his Spanish excursion was merely an invention, and that he travelled no further than to the British Museum; whereas, if he really did visit Burgos and the other places he mentions, he must have forgotten to take his eyes with him.

III. A plague upon all description-mongers of the Roscoe, Ritchie, Gore, and Co. genus!—people who only blunder and bungle most dreadfully, when they attempt to speak of buildings, and who, to give them their due, *shirk* saying anything about them at all, if they can possibly avoid it, and find any other filling-up stuff, no matter what, so that it does but eke out the quantum of pages, which is all many publishers care for, or indeed, the "intelligent public" also. The letterpress to Pugin's Paris is a precious specimen of this sort of description; done, it would seem, by one of the publisher's shopmen or porters. The blunders and proofs of ignorance are innumerable; and no wonder, when the writer does not even know the difference between a portico and a portal. Nevertheless he has shown some contrivance, in contriving to give *descriptions* of plates, without saying a word relative to their subjects. Such is the case, for instance, in regard to the view of the staircase of the Chambre de Paris, where not the slightest information of any kind is afforded—not even so much as a syllable.

IV. Pedantry, I am happy to say, seems to be far less rife among the juniors of the profession, the rising generation of architects, than it has been among their predecessors. They seem to be imbued with more artist-like feeling, and willing to shake off the trammels of rules in themselves merely conventional, and little better than hindrances and obstacles, when allowed to interfere with æsthetic principles. Probably Professor Hosking has contributed in no small degree towards this very desirable liberalism in architectural taste, by the remarks contained in his "Treatise," and by the courage he showed in venturing to impugn the authority of Vitruvius, whose writings may certainly now be dispensed with, or retained only for their philological value, since we have now become far better acquainted with ancient architecture from actual examples of it, and carefully-drawn delineations of them, than it was possible to be at the time so much importance was attached to the work of Vitruvius. The study of those examples has further tended to show how imperfectly Vitruvius understood his own art, and to what a plodding mechanical system he endeavoured to reduce it. Though he indulges in a great deal of idle pompous verbosity and twaddle,—pretty much as if he was an F.S.A.,—on no occasion does he make a single remark in the spirit of an artist, or say anything that

in the slightest degree amounts to criticism. Of principles he seems to have no idea; on the contrary, he is deplorably dull himself, and his dullness appears to have been hereditary, and to have ever since infected the greater portion of writings upon architecture since his time. It is perhaps—or for "perhaps" I should be inclined to say it is "undoubtedly"—to be regretted that his writings were ever discovered, since they have exerted a most unhappy influence on the art, checking it in the very bud, when it would else have expanded itself, if somewhat more slowly, with greater freedom and geniality. But for that unlucky discovery, architecture would probably never have fallen into the hands of order-mongers, but have been left to develop its powers without artificial restraint, as was the case with the Gothic style.

ROBERT STEPHENSON'S NEW LOCOMOTIVE.

WITH the progress of the locomotive engine, it has, like other machines of extensive use, attained that period when its economy becomes of the greatest importance. Influenced by such considerations, Mr. Robert Stephenson has directed his attention to a less consumption of fuel, and to effecting a more simple arrangement of the machinery, both of which points have been well managed in his new engine now running on the York and North Midland Railway.

Economy in the consumption of fuel has been obtained, by adding considerably to the length of the tubes, without increasing the distance between the front and back axles of the engine; consequently the space occupied by the engine upon the bearing is precisely the same, therefore no alterations are requisite in the turn-plates, or other arrangements made for the accommodation of the ordinary locomotive. The machinery is simplified by placing the axles of all the wheels under the cylindrical portion of the boiler, the axle of the front wheels being placed close to the smoke box, and the axles of the hind wheels close to the foremost end of the fire box, instead of the back part. This arrangement allows the axle of the driving wheels to be placed in the centre of the other two axles, or at such intermediate distance as may be found the most suitable for the moving parts.

The alteration in the construction of the boiler and tubing gives a heating surface of 800 superficial feet, whereas in the ordinary engine it rarely exceeds 450 feet, being for the new plan a superiority of fully 350 feet. Such is the effect produced by this addition, that the temperature of the air escaping in the chimney scarcely exceeds the temperature of the water in the boiler; a circumstance which has a farther beneficial effect beyond the economy of fuel, for it has been found, by increasing the extent of heating surface, and employing usefully the whole of the heat generated in the fire, that a less violent draught of air is required; the consequence is that very few hot ashes are thrown out of the chimney; this peculiarity is quite remarkable in the engine now running. A few days since, a journey of 90 miles was performed by this engine, during which no ashes were thrown out of the top of the chimney, and at the same time the accumulation in the smoke box was very trifling, not exceeding a fourth of the usual quantity. As the tendency to eject ashes from the chimney is dependent upon the speed, it is necessary to state, that the speed was never below 20 miles per hour, generally exceeded 30, and for several miles a speed of 43 miles per hour was uniformly attained, with five loaded coaches.

The consumption of fuel during the above experiment was 19.2 lb. per mile, with a load of 8 coaches over half the distance (45 miles), and 5 coaches over the remaining half. This consumption includes the whole of the fuel used in lighting the fire and raising the steam.

We may truly say, that we have never witnessed an instance where speed and economy were combined to the same extent; indeed, under no circumstances have we heard of the consumption of fuel being reduced to so low a figure. It must, however, be borne in mind, that this

result is from a single experiment, and that we must not be deluded by isolated trials; but we are glad to hear that on the line where the engine is now working, the Company have ordered an accurate record of the performance, and quantity of fuel consumed during each trip, which we hope will be made public.

Mr. Stephenson has introduced tubes of wrought iron, instead of brass or copper, in order that the increased heating surface might be obtained without a corresponding augmentation in the price of the engine. This he has not adopted without making several experiments. During the last twelve months, he has had several boilers working under his own eye with iron tubes, for the special purpose of determining how far he could recommend them for general adoption. The result has been all that he could desire; and it is owing in some degree to this, that he has introduced them with greater confidence.

Having now described the modification in the boiler, we shall proceed to point out Mr. Stephenson's alterations in the mechanical arrangement. In the ordinary engines, the mechanism for working the slide valves is very liable to derangement, and considerable wear and tear. This part of the engine he has so far simplified, as to require only a simple connexion between the eccentrics and slide valves, thus doing away with a considerable number of moving parts, which have hitherto given rise to more casualties than any other part of the ordinary engine. This is attained, by placing the slide valves vertically on the sides of the cylinders, instead of on the top, as heretofore, so that the direction of the sliding motion of the valves, and the central line of the valve rods, will intersect the central line of the main axle, at the point where the eccentric is placed. In this case, the eccentric rods are connected immediately to the prolongation of the valve rods, without the usual intermediate levers and weigh bars; besides the slide valves of both cylinders are placed in one steam chest, between the cylinders.

Another improvement is that effected in the working of the feed pumps: it consists in connecting the pump rods to the eccentrics used for reversing the engine. By this arrangement, the velocity of the moving part of the pump is greatly diminished, by which is secured greater regularity of action. In addition to what we have already described, there are several minor alterations, which we cannot fully explain without giving detailed and elaborate drawings.

The following are the principal dimensions of the engine now working on the York and North Midland Railway:—

Diameter of cylinder	14 inches.
Length of stroke	20
Diameter of driving wheels	5½ feet.
Ditto of small ditto	3
There are 150 tubes, giving a heating surface of	765
Copper fire box, with a heating surface of	30
Total heating surface	795 feet.
Length of boiler, including fire and smoke boxes	17 feet.
Weight of the engine in working order	15 tons.

ON THE ORIGIN AND HISTORY OF THE OBLIQUE ARCH WITH SPIRAL JOINTS, AND THE VARIOUS SUBSTITUTES FOR IT.

MR. EDITOR—The interest taken by you in this subject is fully evinced by your inserting in your journal of 1840 several papers by the following authors: Edward Parry, C.E., Edinburgh; B. H. B., Edinburgh; G. W. Buck, W. H. Barlow, Peter Nicholson; and in 1841 by W. H. Barlow, Peter Nicholson, and G. W., York; I therefore trust you will find me a corner, being an original subscriber to your very valuable journal, for some observations on the same subject.

The following are the writers on the oblique arch in the order of time:—

Rees' Cyclopædia, title, Oblique Arch, by William Chapman, C.E.; Encyclopædia Britannica, On the Oblique Arch, by Thomas Tredgold; Treatise on Masonry and Stone-cutting, 1828, by Peter Nicholson; Paper read before Literary, Scientific, and Mechanical Institution of Newcastle, June, 1833, James Losh, Esq., Recorder of Newcastle, in the Chair, On the Origin and Progress of Architecture, and of the Arch in particular, and especially to show that W. Chapman was the inventor of the Oblique Arch—by Henry Glynn, Newcastle; London and Edinburgh Philosophical Journal, a paper on the construction of Skew Arches, by Charles Fox, April, 1836; ditto, March, 1837; London and Edinburgh Philosophical Journal, A Letter from Henry Welch, Newcastle, to Peter Nicholson, March, 1837; Society of Arts, Edinburgh, A Paper by Edward Sang, C.E., on Oblique Arches, read Nov. Dec., 1835, Jan. 1836, and May, 1838; Treatise on the construction of Oblique Arches, by James Hart, Mason, Weale, 1837; Essay on Oblique Bridges, by George Watson Buck, July, 1839; Treatise on the Oblique Arch, by Peter Nicholson, published in parts, part 1 published Jan., and part 2 in May, 1839.

The following are the facts, as brought forward in the paper of Henry Glynn, claiming the honour of the invention for Mr. W. Chapman. In the article in Rees' Cyclopædia, Mr. Chapman says "It occurred to him" that each course of *voussoirs* should be rectangular to the face of the arch, and their beds spiral, and their soffits curved in that direction, and twisted in their sommering, and that the head of each *voussoir* in the acute angle of the bridge would make an obtuse angle with its soffit decreasing towards the brim, whence it becomes acute, and increasing as it approaches the other abutment. The beds of the *voussoirs* are also twisted, and under equal widths of bed, the space between the intrado and extrado are increased upon the face, as the haunches are approached (in the proportion as the secant of their angle of deviation from a rectangle, with a line drawn between each extremity of their soffit). The joint at the centre of the arch is only rectangular from the face, the others diverging towards the obtuse abutment, and increasing as the haunches are approached, and converging towards the obtuse abutment. The development of the face line of arch convex where acute with abutment, and concave with the obtuse abutment. This curve he calls Polygonic, and the convexity will depend upon the versed sine of the arch, and that the form of arch to be preferred is the flat segment; that the head of each *voussoir* on the acute angle makes an obtuse angle with its soffit, decreasing as the crown is approached, thenceforward becoming acute, and increasing as they approach the obtuse abutment. Finlay Bridge near the town of Naas, over the Kildare Canal, a branch from the Grand Canal, was erected by him in the year 1787, on the above principles. It is 25 feet span, with a rise of 5½ feet, and the obliquity is 51°, or its supplement 39°. Mr. Chapman says "since the above period the plan in a few instances has been followed; the same idea may have occurred to others, although he never heard of it." Mr. C. was a native of Whitby, Yorkshire, and practised extensively as an engineer in Ireland, and died at Newcastle-on-Tyne, 1832. He was a member of the Royal Irish Academy, and of the Institute of Civil Engineers, London. In the works of the writers on this subject since Chapman's time, no new principle has been developed, but only more improved modes of working the arch stones; and none of the writers notice Chapman, except Peter Nicholson, who tamely says, "He seems entitled to the honour of originating the idea of oblique bridges in their present form, but he does not appear to have laid down any sound principle by which it might be done;" and even this brief notice is suppressed in the second edition, and in many copies of the first of Peter Nicholson's work.

Previous to Chapman's bridge, all bridges of this description had been built with the *voussoirs* laid parallel with the abutments, and their ends bevilled off in the direction of the roadway, and had been carried by this means to an obliquity of 15° from a right angle; and for others, where the obliquity was greater, the arch was turned square, and the parapets curved in the direction of the roadway, leaving alternate triangles outside them.

The following bridges have been built on Chapman's principle:—

1 on the High Peak Railway, 1829. Thomas Jackson Woodhouse, Engineer.

1 on the Stockton and Darlington ditto, 1825. John Dixon, Engineer.

1 on the Great North Road, three miles north of Newcastle, on the road to Morpeth.

15 on the Liverpool and Manchester Railway, 1830, of the following spans—14 ft., 15½ ft., 31 ft., 26 ft., two 38 ft., 47 ft., 32½ ft., 34 ft., 33 ft., three 30 ft., 54 ft., and one of two arches, 65 ft. span each. The one 54 ft. span is built at an angle of 56°, or its complement, 34°, at Rainhill, and wholly of ashlar. George Stephenson, Engineer.

1 on Hartlepool Railway, at Castle Eden, 1834.

Several on the York and N. Midland; 1 over the river Aire, 65½ ft. span, at an angle of 60°; 1 over the Calder, of three arches, 50 ft. span, at an angle of 75°; the arches are brick.

9 Newcastle and North Shields, of small spans, 18 ft. each, 1839. Robert Nicholson, Engineer.

Great North of England Railway, bridge over the Tees at Cross, 1839; four arches of 60 ft. span, being segments with a versed sine of 14½ ft., built at an angle of 50°. The height of the bridge is nearly 70 ft. from the water, and measured from out to out of parapet, in the square, is 23 ft. 9 in., whilst, measured in the direction of the abutment, the length is 37½ feet; 19 courses of the arch stones spring from an abutment, and 44 are independent of either, (each stone is 13½ in. broad on the soffit, 19½ in. long, and 2½ ft. in depth,) making a mass of stone in each arch, without including the haunches or parapets, of 300 tons weight, suspended in mid air, capable of bearing as many tons more passing over it, at the rate of 30 miles per hour. Truly this is a work of which modern science may be proud. This magnificent work was designed, and superintended during its execution, by Mr. Henry Welch, the surveyor of bridges for the county of Northumberland.

On the Brandling Junction Railway, 1 bridge 38½ ft. span, with a versed sine of 6 ft., segmental at an angle of 76°, 1839. John Benj. Green, Architect, Newcastle.

1 on Midland Counties Railway, near Sawley, 30 ft. span, built wholly of ashlar, at an angle of 45°. Thomas Jackson Woodhouse, Engineer.

The extraordinary expense in executing the oblique arches, coupled with the risk of insecurity when carried to any large extent, has induced engineers to find some other material than stone, and the following plans have been adopted. In the year 1827, Mr. Leather, of Leeds, constructed a bridge at Monk Bridge, near Leeds, and another in 1833, at Hunslet, near Leeds, both of cast iron, on an ingenious and novel plan, viz. two arches of cast iron, with the roadway suspended below. This principle has been adopted on the London and Birmingham Railway, and the North Midland at Derby. Wooden arches on the laminar principle have been similarly used by J. B. Green, of Newcastle, and framing on the Schaffhausen plan, by Mr. Blackmore, engineer to the Carlisle Railway. Cast iron arches and girders have been extensively used, by building the abutments askew, and placing the girders in the direction of the intended roadway. There is one of cast iron, of 47 ft. span, over the Uppingham Road, on the Midland Counties Railway, Thomas J. Woodhouse, Engineer; one on girders, 37 ft. span, over the Paddington and Grand Junction Canal, on the Great Western Railway, I. K. Brunel, Engineer; on the Manchester and Birmingham Railway, over the Fairfield street, Manchester, G. W. Buck, Engineer; a cast iron arch, of 128½ ft. span, at an angle of 25°. The abutment is in the line of the street, and the arches placed in the line of the railway, 6 ft. apart, and the stone abutment above the springing line, set back square, with the end of each arch or rib so as to form its abutment on the principle of a common square bridge.

On the Midland Counties Railway, where the Loughborough and Stamford road is carried over the railway, Mr. Woodhouse has erected a bridge wholly of brickwork, on the principle of the iron bridge of Mr. Buck. The ribs of brickwork, if we may use the term, are elliptic, 42½ ft. span, with a versed sine of 11 ft., and are 4 ft. in breadth, measured on the square. The soffit of the arches, or ribs of brick are level or flush, in the direction of the centre of the railway,

ut are not so in any other direction, dipping below each other in succession, and increasing gradually as the abutments are approached, being greatest at the obtuse end of the abutment. The above is a unique specimen, being the only one ever erected, and is the bold invention of Mr. Woodhouse, and was erected in 1839-40.

I trust that, as the origin of the arch in architecture, as also the time of the introduction of the pointed arch, are both lost in the annals of time, it will be a sufficient ground for your republishing, at full length, the article of Chapman in Rees' Cyclopædia, that the time of the introduction of the oblique arch may be more fully known, and the real inventor have his due meed of praise. This is certainly due to the memory of Chapman, and I trust, from the principles developed in the paper of Henry Glynn, as first promulgated by Chapman, will justify me in coming to the brief conclusion, in respect to the other writers on the subject, that they have developed no new principle, but only improved the mode of working the stones, and perhaps mystified the subject with unnecessary technicalities.

I am, Sir,
St. Ann's,
Newcastle-upon-Tyne.

Your's obediently,
OLIVER TWIST.

MR. CHARLES WYE WILLIAMS AND HIS BOILER PROJECTS.

CONSIDERABLE attention has been lately excited by the disquisitions of Mr. Charles Wye Williams, respecting two alleged inventions of his, one of which has for its object the prevention of smoke, and the other the increase of the evaporative rate of boilers, by studding them over with spikes, "like quills upon the fretful porcupine." In the belief that an analysis of these projects will be acceptable to our readers, and may possibly be beneficial to this gentleman himself, we are induced to offer a few observations respecting them.

Let us first anatomize the spike boiler plan. The following account of this notable invention we extract from the 950th number of the *Mechanic's Magazine* :—

"When the gases which are the products of combustion (and which contain all the heat arising from such combustion) pass along through the flues impinging against the surface of their metallic plates, the heat is conducted in a direction at right angles to these surfaces, to the water in the boiler. This then may be called *transverse* conduction, as the heat passes transversely through those plates. But if we heat one end of a rod of iron, we find a very large conducting power is brought into action, by reason of the heat passing *longitudinally* along its fibres, and with great rapidity. This may, therefore, be called *longitudinal* conduction, in contradistinction to the former *transverse* conduction. Now this is the power, or modification of the power, of metallic conduction, which it is proposed shall be rendered available, and the application of which is at once so practicable and effective.

"Independently of the conducting power which a metallic pin of any size may have, it is manifest that it possesses an absorbing or receiving power, in proportion to its length as well as its diameter, and this it is which gives it an available applicability in the flues of boilers. Suppose an iron or copper pin, of half an inch in diameter, inserted into a metallic plate, and projecting 3 inches beyond its surface. In that case, a portion of such surface plate, equal to a circle of but half an inch in diameter, is occupied, while the pin itself presents a heat-receiving surface equal to 4½ inches, or as 9 to 1. If this projection be presented to the stream of heated gaseous matter in the flue, we obtain an effective heat-receiving surface, nine times greater than the area of the plate which the pin occupies. In other words, the half-inch circular portion of the flue plate which such pin has displaced is thus made to possess the faculty of transmitting as much heat as is received and absorbed by nine half inches superficial."

Well; if this be not carrying absurdity to an imperial pitch, we really do not know what is. Were the evidence of the existence of the scheme less unequivocal, we should be disposed to regard the

whole affair as a hoax, for we are at a loss to conceive how any man, woman, or child, could have seriously propounded such a project. But there can be no mistake in the matter. "The half-inch circular portion of the flue plate which such pin has displaced is thus made to possess the faculty of transmitting as much heat as is received and absorbed by nine half inches superficial," by which we understand, that the pin has the effect of transmitting to the water nine times as much heat as the half-inch disc it displaces. We care not, however, whether this is or is not the precise proportion of alleged beneficial effect. It is plain, that some increased evaporative efficacy is attributed to the use of the pins, otherwise they would not be used; and our reasoning, by a mere numerical adaptation, will be found equally conclusive, whether the ratio of alleged benefit be 9 to 1, or 1,000 to 999. The description of the plan given in the *Mechanic's Magazine* is, we have no doubt, authentic. Mr. Williams is a frequent contributor to the pages of that periodical, and the description of his plan which appears there, carries an internal evidence of having been written by himself. We have said, that the object of the spikes fixed into the iron of the flues is to increase the evaporative power of the boiler. These spikes will of course speedily attain the temperature of those particular parts of the flue where they are inserted; and our philosopher informs us, that all the surface of these iron spikes exposed to the action of the hot air proceeding from the fire is efficient heating surface. If this be true, the rate of evaporation will be about the same, whether we employ a great number of short spikes, or a small number of long spikes, provided only that the quantity of spike surface be the same in both cases; and a single spike will be as efficacious as any given number of spikes, provided it have a commensurate surface. It is manifest, too, that since a given quantity of spike surface is by hypothesis of equal, or nearly equal efficiency to the same quantity of ordinary flue surface, an excellent boiler may be constructed without any flue surface at all, the conduction of heat to the water being accomplished exclusively by the agency of spikes, or by the agency of a single spike. All that is necessary to realize this idea, is to subject sundry connected coils of rod iron to the heat of the furnace; care being taken that the one end of these connected coils is immersed in some convenient vessel of water. The faculty which these coils possess of receiving and transmitting heat in proportion to their surface, will enable them to convey the whole available heating efficacy of the furnace into the water. The heat will very obligingly run through the coils, after the same fashion that lightning runs through a metallic conductor, and an abundance of steam will be generated at the ends of the coils immersed in the water, without any boiler at all. Such is the simple development of this inimitable project. But it is plain that the profundity of our philosopher prevents him from discerning the difference between elevation of temperature and quantity of heat. We shall not insult any school boy, by reminding him, that, rapidity of conduction is *ceteris paribus* simply proportional to the difference of temperature between the hotter and the colder body: now our philosopher says, that if a red-hot bar of iron be cut into two unequal lengths, and, whilst maintained at a constant temperature, the end of each segment of the bar be applied respectively to pans containing water, the end of the larger segment will in the same time communicate more heat to the water than the end of the smaller segment. But to do this, the larger segment must be hotter than the smaller segment, while by hypothesis its temperature is the same; therefore the two bars are of equal and unequal temperatures at the same time, which is manifestly impossible. If a spike of three inches long inserted in a boiler transmit more heat to the water than a spike of one-eighth of an inch long of the same diameter and temperature, it will be necessary to diminish the temperature of the longer spike, to equalise the quantities of heat transmitted by the two. Of two spikes, then, of one-eighth of an inch in diameter, a certain increase in the length of the one is equivalent to a certain increase in temperature of the other; and it might, therefore, on our philosopher's theory, be possible to generate steam, not only without a boiler, but also without a fire. All that is necessary to attain this object is, to have plenty of long spikes; for, as increase in the length of a spike is by supposition,

equivalent to a certain increase of its temperature, a dozen long spikes of a low temperature must be equivalent to a dozen short spikes of a high temperature. An indefinitely long spike, therefore, cannot but communicate heat to water, whatever be its temperature, provided it be not at the point of absolute zero. According to the same doctrine, a pint of boiling water is only half as hot as a quart of boiling water; and as to a spoonful—why a spoonful of boiling water can only exist in the shape of ice. We should be sorry to deprive Mr. Charles Wye Williams of the credit of a project which involves such important and reasonable deductions.

We can foresee, that to all we have said it will be very triumphantly objected by our philosopher and his satellites, "The accuracy of the doctrines you impugn has been demonstrated by experiment." We cry your mercy, gentlemen; that is certainly a poser: yet, though we cannot fail to be convinced by such an argument, we unhappily are not converted. We retain certain qualms and conscientious scruples, which disenable us to embrace the creed of our philosopher; yet we cannot be insensible to his extraordinary merits as an experimentalist, whereby he has obtained results such as no one else is able even to verify. Upon this part of the subject we refrain from enlarging, seeing that we do not possess the power of manufacturing facts *ad libitum*.

Some of this gentleman's partisans, who happen to possess sense enough to see the absurdity of his spike-boiler theory, have offered another explanation. The hot air, in its passage through the flues, say they, quickly gives out the heat originally resident in its upper stratum. The upper stratum of air is therefore comparatively cool, whilst the air in the central part of the flue is exceedingly hot. The spikes, they contend, by virtue of the impediment they offer to the passage of the hot air, create eddies within the flue, which mingle the two strata, and facilitate the absorption of the heat. But it is a fallacy to suppose that two strata of air, of great difference in temperature, can continue in juxtaposition, with the heavier stratum uppermost. And even were the case otherwise, the employment of spikes rivetted into the boiler is not essential, to produce the desired effect. Any other equally impeding substances would be equally beneficial; and fire brick would answer just as well as iron or copper. The explanation fails; yet it has the merit—a negative one certainly—of being unattended with glaring inconsistency; and it manifests the extremely reputable desire on the part of this gentleman's attendants to moderate the wildness of his speculations, and to insinuate him with a few grains of common sense. But it all will not do; madmen will sometimes elude or overpower their keepers, and perform their antics before every passer-by: and this gentleman will write and will print, whatever may betide. It would be hopeless to attempt the extinction of the *cacovites* of a being that will rather stand in the pillory than remain unnoticed.

Let us proceed to consider the smoke-preventive plan. From what we gather from this gentleman's book, and from circulars and advertisements, we conclude that his invention for the extinction of smoke is founded upon a principle differing entirely from that of all pre-existing plans: that instead of endeavouring to burn smoke, as others have vainly attempted to do, he aims at preventing the formation of smoke, and that hence arises the unprecedented efficacy of his plan. The distinction is certainly an important one: and the chemical views which indicate the superiority of the smoke-preventive principle are indisputably correct, as will be apparent from the following remarks:—

"The combustion of smoke, as an obvious means of economizing fuel, has been frequently tried, and the attempt as frequently relinquished. The great waste resulting from smoke, the product of imperfect combustion, which must be estimated not merely in the proportion of its unconsumed carbon, but also in regard to the heat which becomes latent in its formation, and is dissipated with it in the atmosphere; and the many inconveniences which are consequent on its production, are such as to render it expedient that all schemes professing considerable economy in fuel should make the removal of these defects their starting point. Many plans have therefore been devised, and some of them of considerable ingenuity, for burning that smoke

which in ordinary furnaces coal must of necessity produce, and some of these perhaps would have been completely successful, except for the radical defect they had all to contend against, originating in the chemical composition of smoke, which, once formed, can never be completely consumed without the admission of so much air as will by its cooling agency more than compensate for whatever heat the combustion of the smoke occasions. Smoke may therefore be regarded as a mixture of combustible and incombustible gases, in such proportions as to prevent the combustion of the mixture with practical economy; the incombustible portion being chiefly composed of nitrogen and carbonic acid, which prevent the combustion of smoke, on the same principle that water shaken up with it prevents the inflammation of oil. Hence the attempt should be, not to burn that which is in its nature incombustible, but to ignite the gases extricated from the coal immediately on their evolution, and without affording them the opportunity of becoming commingled with the unflammable products of combustion.* In other words, it is gas, not smoke, that should be attempted to be burned; and this it is that this gentleman professes to do. The distinct enunciation of the smoke-preventive principle, as being susceptible of practical application, and as pregnant with the most important effects, is one thing; the contrivance of the means proper for the successful application of this principle, is another thing: and we are quite willing to render to this gentleman whatever honour appears to be due to him, for a priority in either of these achievements.

All smoke-burning projects operate upon the principle of admitting an excess of air into the furnace or flue, and this principle is attended with two insuperable and fatal objections. First, the refrigerating effect of the great excess of air it is necessary to admit to a mixture of combustible and incombustible gases, to accomplish the indispensable condition of combustion—proximity of the atoms to be combined; and second, the impracticability of apportioning the admission of air to the ever-changing quantity of smoke evolved from an ordinary furnace. Smoke-burning furnaces, therefore, although they have in some well-authenticated instances succeeded in accomplishing a saving of from 12 to 14 per cent., with the attention accorded to novel and experimental projects, have in the aggregate of ordinary working invariably been productive of a diminished efficiency, or an increased consumption. Though again and again revived, the project of smoke-burning has as often expired of perfect inanition. Yet each successive projector has had some modification to propose, which it was alleged would render success inevitable. Thus, one having admitted the air through a round or square hole, and having failed in realizing a satisfactory result, another has attributed the failure to the indiscretion of not having admitted the air through a slit, and has based his proceedings upon that discovery. One has worked with the assistance of an air valve, and another without that assistance. One has transmitted the air to the smoke through orifices in the sides of the furnace immediately above the bars of the grate; another through a hollow bridge, and a third through pipes which carry the air into the flues; the efflux of the air being in some cases through one hole, in other cases through many holes. But it is plain, that all such modifications as these leave the real difficulties of the case untouched; inasmuch as there remains the same necessity to admit a great excess of air, to accomplish anything like complete combustion, and the same impracticability of adjusting the quantity of influent air to the variable conditions of the fire. These difficulties are not inseparable from the smoke-preventive system; and we were therefore warranted in expecting from Mr. Williams some contrivance from which they would be altogether excluded, and which might be regarded as an incarnation (so to speak) of the principles of smoke-prevention. But the parturient mountain has again brought forth a mouse. This learned philosopher, after vapouring about atoms, gases, and prevention, throughout the length and breadth of an octavo volume, presents us with—what? a veritable antique smoke-burning furnace. A smoke burning furnace? Yes, readers, 'tis even so. You may well be

petrified at this most lame and impotent conclusion. Yet so it is. Our philosopher, after raising us to the tip-toe of expectation, by promising to shew us, NOT how *smoke may be burned*, but how *coals may be burned without smoke*, ruthlessly demolishes the fairy fabric our fancy had created, and congeals us into stone, by holding up a Medusa's head, in the form of a smoke-burning furnace, of which the sole peculiarity is, that the air enters by a greater number of holes than usual. Whether of two smoke-burning projects the least exceptionable is that which admits the air at one hole, or that which admits the air at many holes, it would be irrelevant at present to inquire. Our own predilections are in favour of the latter method; though we are by no means prepared to maintain, that the admission of the air through a few judiciously disposed long and very narrow slits might not be greatly preferable to both. At present, it is sufficient for us to show that this gentleman's furnace operates not upon the smoke-preventive, but upon the smoke-consumptive principle; that it is a mere smoke-burning furnace, attended with the objections we have already mentioned as fatal to smoke-burning plans.

To the proof then. At the back of the fire bridge of this gentleman's furnace the air is admitted through a number of minute orifices, and mingles with the æriform matter proceeding from the coal upon the bars of the grate. There are no means provided of regulating the quantity of air admitted through these minute orifices, other than pre-existing smoke furnaces possessed. The only question therefore to be decided is, whether the æriform matter proceeding from the coals on the bars of the grate is gas, or smoke. To determine this it is necessary first to ascertain whether combustion does, or does not take place, in the furnace during the evolution or production of the said æriform matter. Our philosopher says that combustion does not take place, inasmuch as he has doors to his ash-pit which he shuts immediately that the furnace has received a charge of fresh coals, and which he keeps shut until the gas is all expelled. If this be done any æriform matter presented for combustion at the anterior air orifices, will certainly be *not smoke but gas*. If on the other hand combustion take place within the furnace during the carbonization of the coal, the æriform matter presented for combustion at the air orifices, will be *not gas but smoke*. The question therefore resolves itself into this Does or does not combustion take place in the furnace during the carbonization of the coal? Now if combustion do not take place in the furnace during the carbonization of the coal, and as the volatilization of the unfixed parts of the coal requires a large amount of heat for its accomplishment, there must be some available source of heat other than combustion from which the requisite quantity is supplied, our philosopher says that the red hot embers of the fire are this source of heat. But it is manifestly impossible for any body to give out half its heat to another body and remain as hot or nearly as hot itself. Besides the great quantity of heat which becomes latent when solids or liquids are transformed into gases, is left without any provision. A very simple computation would show—the weight, temperature and specific heat of the incandescent embers, and the weight, temperature and latent heat of the gases, (or what is equivalent—their weight, temperature, volume and specific heat) being given—that no practicable method of working this gentleman's furnace, would render the embers on the grate an adequate distributor of the heat requisite to expel the gases resident in the coals which constitute a charge of the furnace. But it would be preposterous to resort to Algebra to establish a self-evident proposition. Every one knows that if green coals be thrown upon a fire, and at the same time air be excluded, the coal will not be carbonized, but the fire will go out: and even in a coke oven carbonization will remain unaccomplished, unless air is admitted. If this effect be consequent upon the exclusion of air even where the process of carbonization is *aided* by the heat of a mass of incandescent brick work, how preposterous would it be to conclude that carbonization can take place in a hermetically sealed boiler furnace, where the process is *impeded* by the refrigeration of the water of the boiler! If then there is no combustion in this gentleman's furnace, and if at the same time gas is evolved, there remains no conceivable source of the heat absorbed during volatilization, except the act of volatilization it-

* Though's on Steam Locomotion. London: Weale, 1840.

self; and to say that this is the source of the heat, is tantamount to saying that cold water is not merely able to raise itself into steam, but to leave a considerable surplus of heat after having done so. We have no alternative then but to conclude that combustion does go on in this gentleman's furnace, if it be in action at all. If there is combustion, that combustion is either perfect, or imperfect: if perfect, there is no necessity for any appliance, either smoke consumptive or smoke preventive: if imperfect, it is not gas but smoke that is evolved, for the very definition of smoke is the product of imperfect combustion. This furnace is therefore a smoke generating, and consequently a smoke burning furnace. He may say otherwise. He may call it a patent Argand, or patent any-other-and, but a smoke burning furnace it is, and we defy him and his legion of chemical professors to prove the contrary.

Upon what ground then can we be called upon to believe that this smoke burning project will be one whit more beneficial than other smoke burning projects, in all essential points identical with it? And what shall we say of those who have lent themselves to the reputable endeavour of puffing off the paltry nostrum? Of such men as Mr. Brande and Dr. Ure, it is painful to be obliged to speak in any other terms than those of commendation and respect. Their names are household words: and we are distressed at anticipating the possibility of such names becoming epithets of contempt, instead of continuing to be expressions of reverence and admiration. We trust therefore that the attempt to elevate this ponderous gentleman, will be relinquished. The attempt exhibits much good nature, but very little good sense—and it *must* be unsuccessful. A tortoise can never be taught to fly by being hoisted into the air—and though a dunghill cock may by dint of extraordinary exertions wing a flight of 20 yards at the height of three feet above the surface of our planet, yet the achievement only serves to show that he is any thing but an eagle, and that his native mire is his most appropriate element. There is no real kindness in trying to raise this gentleman out of his appropriate and very humble sphere; and is Mr. Brande so confident of the imperishable virtue of his laurels as to suppose that they have nothing to suffer from so ill judged an attempt? Is Mr. Brande likely to enhance his own reputation, or the value of his art, in the estimation of practical men by telling them that the product of the destructive distillation of coal is rendered unflammable by mixing with the cold air in the chimney, and at the same time praising a project possessing to correct the evil by introducing a still larger quantity of cold air into the flues than is usual? Of Dr. Ure's attainments in every department of the philosophy of the arts there can be but one opinion; and we should perhaps attach a value to his praise commensurate with our sense of his ability, had we the assurance that he was a landed proprietor of ten thousand a year, which we regret to find is not the case. It is really a reproach to this country that abilities like Dr. Ure's should be wasted in the ignoble occupation of compiling or revising specifications of patents, and furnishing encomiums to patentees; and we do trust that the award of some adequate place or pension to this distinguished philosopher, will speedily remove such a stigma from our land. As to Doctor Kane of the Apothecaries Hall, Doctor Brett and Mr. Something a chemist of Leeds, we need only say that we shall not condescend to notice such celebrated gentlemen, further than to assure them that they would find much more reputable occupation behind their counters dispensing mercurial pills and doses of Glauber, than in soliloquising about things of which they know nothing. They may save themselves the trouble of casting their perfume upon the violet. Engineers and boiler makers know their business much too well to lack instruction from a pack of effervescent chemists and druggists.

Having shown that this gentleman has failed in producing any contrivance capable of giving practical efficacy to the smoke preventive principle, it only remains that we should ascertain whether he is entitled to the merit (if it be any), of having been the first to suggest that principle—the first to distinctly enunciate the doctrine that the smoke preventive principle is practically applicable and peculiarly beneficial. The circumstance of having himself failed of making any practical application of this principle, does not deprive him of what-

ever honour may be attached to the distinction of having been the first to suggest it for practical application in the furnaces of steam boilers. This point must be decided chiefly upon the evidence of dates, and as the inquiry is only of collateral interest, we must hurry over it as quickly as we can.

The first edition of Mr. Williams's book on combustion was published in 1840, but *posterior* to the essay entitled "Thoughts on Steam Locomotion," published the same year, from which we have already given a quotation. This essay is anonymous, but is, we understand, ascribed to Mr. Bourne, and it contains a clear though a concise exposition of the principles and advantages of smoke-prevention. This gentleman's patent was, it is true, taken out in 1839; but Mr. Bourne, we are informed, has a patent for the same thing, of the date 1838, and a paper descriptive of this patent, written in 1838, and now before us, describes the patent to be for the "prevention of smoke, and economization of fuel." We have also before us a copy of a letter written by Mr. Bourne in 1837, of the date September, which develops in the first place, the hopelessness of the endeavour to burn smoke; and in the second, the benefit derivable from the smoke-preventive principle, which is shewn to be practically available. "Smoke," says this letter, "cannot be effectually burned; the object should therefore be to prevent its formation." We have also before us reports by Dr. Lardner and Mr. Farey, of the date of January, 1838, relative to Mr. Bourne's invention, and other papers and documents, which it is unnecessary to mention. Now, up to the end of 1837, Mr. Charles Wye Williams had done nothing whatever in smoke-prevention. In 1838, even, he was occupied, not with schemes for the prevention of smoke, but with projects for making resin and other artificial fuel—projects, of which the smoke-preventive project was the immediate successor,—whilst we have evidence which shows that Mr. Bourne's experiments tentative and illustrative of the advantages of smoke-prevention, extend as far back as 1834, years before this gentleman had turned his attention to the subject.

So far we have only shown that Mr. Williams has no pretensions to that priority in the development of the superiority of the principle of smoke prevention claimed for him by some of his certificate-mongering encomiasts. Let us go a step further and inquire whether he is entitled to the merit of independent development or invention. He *may*, at the time he commenced his operations, have been in perfect ignorance of all Mr. Bourne had previously said or done. Our readers will find little difficulty in concluding whether or not he *was* in ignorance, when we inform them that the letter which we have already mentioned as containing a complete development of the principles and advantages of smoke-prevention, written in September, 1837, was addressed to Mr. Williams himself, confidentially, at his invitation; and that it was shortly after the reception of this letter that Mr. Williams threw aside resin fuel, compressed peat, and a host of kindred projects, and commenced might and main upon his own account, on the smoke-preventive plan.

ON EXPLOSIONS OF STEAM BOILERS.

In another part of the *Journal* we have given the evidence taken before the coroner at an inquest held in consequence of the death of several individuals, occasioned by the bursting of a boiler at Messrs. Elce & Cottam's manufactory at Manchester. We now have an opportunity of giving the translation of a letter from Mr. Jobard, of Brussels, to the Baron Seguier, on the principal cause of the explosion of steam boilers, which may throw some new light on the cause of the accident.

"When the water in a boiler becomes so low as to leave some part of the sides exposed to the direct action of the fire, those parts are raised to a red heat; the received opinion is, that the steam, coming in contact with the heated iron, is decomposed, and forms hydrogen

gas, but not to such a degree as to become explosive, because a considerable quantity of oxygen, or atmospheric air, which does not already exist in the boiler, is required to render it so. It is, however, this very air, which, I consider, does really enter the boiler in considerable quantity, and is evidently supplied by the feed-pump itself, which, from some cause or other, although it continues at work, thus permits the water to lower in the boiler. In such case every stroke of the pump injects a certain portion of air into the boiler. There might also exist a slight crack, or a defect in the working barrel, or in the packing of the stuffing-box. These defects would cause the feed-pump to become a real air-pump, if any accident happened to the valves of the induction pipe, or if the water in the reservoir got below its proper level. There can be no doubt that these accidents do occur.

"Let us now examine what takes place when atmospheric air is thus forced into the boiler. This air passes through the remainder of the water in the boiler, and occupies the space above the injection pipe, without being immediately mixed with the gas, which continues to be produced from the heated sides of the boiler, but so soon as the engine is set to work, a considerable ebullition is produced in the water, and a detonating mixture of air and gas is formed. So soon, therefore, as this explosive mixture comes in contact with the heated surface of the boiler, it inflames in the same manner as carburetted hydrogen gas does against the wire of a Davy's lamp when heated to a cherry red.

"There is also another means of accounting for the firing of the explosive mixture, namely, by the electric spark which is formed every time that the steam is struck or forcibly pressed by the edges of the valve, as was shown in the experiments made by the Commission at the Museum, and as you yourself witnessed in those with the engineer Tassin. The experiments of Lavoisier show that if a valve be opened at the moment the explosive mixture is in contact with it, the slightest electric spark is sufficient to cause an explosion. It might also happen that the disc of the valve produced the effect of the plate of the electrical apparatus, and caused the spark on being lifted from its seat.

"This will account for the greater part of the explosions happening at the moment the engine is set to work, or the valve opened, as occurred on the 13th of November, 1841, at the manufactory of Messrs. John Elce and Cottam, at Manchester.

"There can be no longer any doubt as to the production of hydrogen gas in boilers where the water is deficient, since the dangerous experiment made by Mr. Goldsworthy Gurney, when he proved that the steam emitted from a boiler heated red hot (the feed pumps being stopped and the water suffered to get low), burnt like hydrogen gas: the only reason that this boiler did not explode must have been, that in this particular instance there was no atmospheric air mingled with the gas.

"In support of this theory, several cases of explosion have come to my knowledge, among others, one that took place at Ghent in the year 1826, which puzzled all the believers in the efficacy of safety valves, as the man-hole was open, and there was no water in the boiler, or fire under it; yet it exploded, and caused great damage. This accident may be thus explained:—

"The boiler had been emptied on the Saturday, in order to clean it on Sunday, leaving only a little water in it to wash it out. This boiler having been emptied before the fire was completely extinguished, must have been heated in parts to a red heat, and thus the steam decomposed. The next morning, the workman, having taken off the man-hole lid, held his lamp, according to custom, within the boiler. The hydrogen gas, rendered explosive by the admission of atmospheric air, immediately exploded, and destroyed the boiler and workshop, and killed the man.

"As the water cannot be thus decomposed in copper boilers, they are consequently not liable to explosion from the cause thus shown.

"In discovering this cause of accident, its remedy is evident; if the reservoir for the feed is placed above the pump, as is invariably done in Prussia, the introduction of air into the boiler becoming impossible.

This arrangement, enforced by law in Prussia, has caused explosions to be of rare occurrence.

"If my opinion on the cause of explosions be correct, and which it is desirable should be verified by official experiment, the regulations at present in use are worse than useless, safety valves become dangerous, and the fusible plates are of no avail. The chief attention ought to be bestowed on the supply of water in the boilers, and then the explosion of boilers rivetted by machinery need not be feared, because the rivet holes become oval before giving way, and permit the steam and water to escape by the seams of the boiler. It is hoped this succinct explanation will enable the proprietors of steam engines to take the necessary measures to avoid explosions.

JOBARD."

ENGINES OF H. M. STEAM SHIP "VIRAGO," OF THREE HUNDRED HORSE POWER.

BY BOULTON, WATT, AND CO. DESIGNED JUNE 1841.

(With an Engraving, Plate II.)

THESE engines are of the kind termed "direct," and were designed to meet the views of the late Board of Admiralty, with reference to the saving of weight, space, and placing all the moving parts below the line of flotation, out of the reach of shot.

They are of the collective power of 300 horses, cylinders 64½ diameter and 5 feet stroke, the velocity of piston being fixed at 215 feet per minute, agreeably to the general rules of the late Mr. Watt.

The Boilers are made to the full power of the engines, as it regards evaporating surface, and occupy 19ft. x 20ft. superficial, and in height they are 12 feet.

The length of the engine room is 53ft. 6in., and the coal boxes are constructed so as to entirely protect the boiler and engines, and contain from 850 to 360 tons of coals, (at 48 cubic feet per ton). The space required by the engines is 18ft. 6in. athwart, and 11 feet fore and aft, that is, over the air pumps, which being placed in the centre of the vessel, occupy comparatively useless space,—for so large a power as 300 horses we believe this to be unprecedented. It will be observed that there are two condensers, air pumps, &c., so that either engine can be worked separately; in consequence of the compactness of the engines, the weight must be very much reduced in comparison with the beam engine.

FIG. 4

ON EGYPTIAN ARCHITECTURE.

IN commencing this subject it is requisite to premise, that we intend to limit the inquiry—except as far as collateral illustration may be requisite to throw a light on the subject—to the temples and palaces of Egypt. A glance at its domestic architecture, as far as our imperfect knowledge in that particular extends, may be permitted. But the sacred cave and the pyramid belong to an anterior period of civilization; that which immediately followed its first stage—the period of cairns and of rough stones, set up for memorials of events. The first cannot be comprised in the term architecture, the latter can. But dissertation on the pyramids and on the pyramidography of Egypt, would burden or complicate the subject, or cause it to deviate from the right track to its appropriate point of view. It would, it is true, furnish materials for a long and elaborate essay. Such an essay might not be uninteresting to the readers of the “Civil Engineer,” nor out of place in its pages; especially after the curious and romantic discoveries of Caviglia, the ardent inquiries conducted on the spot by Colonel Howard Vise, and the recent and elaborate publication of Mr. Perrin, the civil engineer, giving such minute details of the great pyramid’s structure, both exterior and interior, that the most untravelled reader, in his arm-chair, may form as correct an idea of the whole astounding fabric, as the most adventurous traveller who has dived, by the aid of a frail cord, amidst Arab ejaculations, to the bottom of the well, or disturbed the long repose of the bats in the mirky and squalid recesses of the closet over the central room. But for the reason we have assigned, and with a view equally to commodious brevity and lucid order, we shall, as we premised, confine ourselves to the palatial and ecclesiastical architecture of Egypt.

The character of the Grecian temple was grave and dignified beauty, while that of the Ionian was voluptuous elegance. The Roman expressed the ambitious magnificence of the founders. The essential type of the Egyptian temple was sublimity. The sacred edifices of ancient Egypt were impressed with the sublime characteristics of the universal deity to whom they were devoted. Greatness of dimension was so contrived as to imitate infinity by uniformity of succession. On the same principles of succession and uniformity, the grand appearance of all the ancient Doric temples of Greece and Magna Græcia, which may be generally designated as oblong forms with a range of uniform pillars on every side, will be easily accounted for. From the same cause, also, may be derived the grand effect of the aisles in many of our old cathedrals. The long avenues of sphynxes which preceded the approach to the Egyptian temples were constructed on the same theory; long ranges of unbewn stones occupy the same position in forming the approach to the circular temples of the Druids. Denon, Belzoni, and Champollion describe, in vivid and forcible language, the effect produced upon them by the sublime character of the Egyptian temples. Denon says that when the French army came in front of the temple of Tentyra, they were seized with a simultaneous feeling of admiration, and halting on the plain in front of the portico, demonstrated their wonder and delight by a general acclamation and clapping of the hands. Whence did this consummate perfection arise? The architect, in the social scale, was ranked next to the Prince. The art and the artist were studied and valued as they ought to be, in Egypt. An architect was, according to the true definition of the term, superintendent of the works and workmen. He was the creative mind (*nous*) presiding over the mechanical producers of the greatest labours that human ingenuity and labour are capable of creating on the earth.

Certainly the old architects connected all the deepest mysteries and profoundest secrets of theology and science with the forms of architecture, and with the lines, angles, and curves of masonry. Hence arose freemasonry. The Dyonyssiacs who were privileged to build the sacred edifices of Asia Minor, and the theatres of initiation which were attached to the most celebrated, as they were at Memphis and Eleusis, were freemasons. Their first great lodge was possibly the great pyramid; their dramatic mysteries, the origin of the modern

drama, were founded on the judgment of the dead; their secret signs were confessedly derived from the geometrical theology and philosophy of the Egyptian masons, and were handed down to the professors and masters of the monastic architecture of the middle ages, An architect of this class was of necessity imbued with all the theological and scientific knowledge of the sacred colleges. His works may be said to represent the various eras of civilization, and the successive steps of man’s social and scientific progress.

The eye of disciplined taste can readily discern what the common observer cannot—four distinct periods in Egyptian architecture: first, the period of pyramids, cairns, rock-built forts, granaries, treasuries, and sculptured tablets or steles; second, the period of sculptured temples, which succeeded the former, whether troglodyte—i. e. sculptured from the face of the rock—or detached and isolated; third, the period of the rise, progress, and maturity of architectural forms, which may be traced from Osirtesen to Sesostris; fourth, their decline and fall, which may be traced to that period till their total corruption under the Greeks and the Romans. With respect to the first period, as connected with Egyptian architecture, very little can be said. It is to the temples and palaces exhibiting architectural design that we shall confine ourselves. The period, however, exhibits a remarkable analogy, and seems to indicate a particular fact in the history of the first colonization of nations. The architectural and sculptured forms of the first period resemble the sculptured forms preserved on the old temples and palaces of New Spain, ascribed by writers to the Tultecans, who preceded the Mexicans 600 years, or by the native Indians to the Giants, or wandering Masons, a well known designation of the expelled Cyclopean or Shepherd family. It is still more singular, that the monuments on which these sculptures appear, or connected with them, resemble the unvarying characteristics of those which are called Cyclopean, and many may doubtless be ascribed to them without exaggeration. Some of the pyramids erected by them are larger in base than those of Egypt, and composed of equally permanent materials; their rock-hewn Treasuries resemble in every respect the Cyclopean fabric called the tomb of Atreus. Their fortifications resemble similar Cyclopean structures at Tyrians, and elsewhere; and their subterranean sepulchres are approached by similar descending galleries, and distributed into similar sepulchral rooms. Their palaces are characterised by galleries constructed with the well known Cyclopean arch, consisting of receding courses of stone in a triangular form; in one of these monuments, viz, the flower temple of Oaxata, appear individuals precisely like those called the Pomasata, conquered by Sesostris, both in physiognomy, head-dress, and costume. Now were these the same people? were the Pomasata a branch of the Shepherd race? was there any affinity between them and the aboriginal American Indians? We do not affirm it, because the mode of reaching America, either aboriginally or coterminously with Sesostris, would still be unaccounted for. But another remarkable fact should be added, which gives additional reasons for the inference, though it does not prove it. These men are red and beardless, ever the well-known characteristics of the American Indians. Were they then East Indians, as Champollion supposes, and was America originally peopled, as many learned men have argued, from the East Indies, and from the adjacent Indian isles? If, then, the Tultecans, or whatever nation built the monuments ascribed to them, came from the south of Asia, it is quite certain that the Asteks, or Mexicans, came from the north of Asia, and, conquering them, occupied their place; the passage across Behring’s Straits is no great geographical difficulty. With regard to the period, extending from Osirtesen to Sesostris, it is indicated by a gradual rise from primitive simplicity to magnificent and gigantic form; but there is scarcely any difference in the archetypal model of their temples and palaces, or in their sculptured ornaments, except that the first were more primitive, more limited and simple, while the last became successively ostentatious, complicated and magnificent. The second period was equally characterised by troglodyte, as detached temples and palaces. The last period, in which the architecture of Egypt was corrupted by Roman and Greek innovation, requires less comment, as it must be

obvious to the casual observer. The first period is at once distinct and remarkable. The republican forms of government of the great pastoral community, as Aristotle proves in his history of all the first republics, clearly assignable to this extraordinary race, and generally embracing a community of goods, were disseminated throughout the world wherever their wanderings led. These people carried with them in their wanderings all the favourite forms of the pastoral or Cyclopean architecture—pyramids, gateways, triangular or graduated arches without the key-stone, cellular cairns, unsculptured initiatory caverns, irregular courses of colossal masonry, cylindric columns, and rock-built fortresses, which, wherever they are found, attest their presence. These were superseded in Egypt by the more magnificent forms, costly embellishments, and tasteful refinements of the inscribed temples and palaces of the eighteenth dynasty of monarchs who expelled them. The sublime and magnificent monuments erected by this ancient race of monarchs on the plain embraced by "Hundred-gated Thebes," attest to this day their taste, their ambition, their wealth, and their power. They suggest ideas of the works of fabled enchanters rather than of ordinary human beings. Of that Thebes Homer wrote twenty-five centuries ago—

* * * οὐδ' οὐα Θηβας
 Αἰγυπτίας οὐδ' ἑλάνθη δόμοις ἐν κτήματι κείνῃ,
 Αἰ θ' ἐκατομύρια ἐσσι, διηκασιοὶ δ' αὖ' ἐκατόν
 ἄνθρωποι εἰσὶν οὖν ἵπποισι καὶ οἰχομένοι.

It was on that myriad-columned plain, beneath its gorgeous archways and gigantic colonnades, that Champollion, in the excited language of astonishment, exclaimed, "These porticos must be the work of men 100 feet in height! Imagination sinks abashed at the foot of the 140 columns of the hypostyle hall of Karnac." It was there that Belzoni, filled with the fervour of dreamy enthusiasm, which, as he says, raised him above the petty cares of mortality, pronounced his joyful *Eureka*, and exclaimed, "I have at least lived one day."

"It appeared to me," he added, "like entering a city of giants, who, after a long conflict, were all destroyed, leaving the ruins of their various temples as the only proofs of their former existence." One brief passage will depict the architectural ambition of these great monarchs. Our well-known column called "the Monument" has been deemed a wonder. The great hall of Karnac was supported by 140 columns, most of the same diameter, and some of two-thirds the height of that "Monument." The illustrations of Rossellini and Champollion prove that imagination itself has scarcely invested this line of potentates with attributes of too surprising a character.

A few preliminary words on the domestic architecture of Egypt, may be expedient for the purpose of clearing the ground. One step led from the sacred cave (*heron antrou*) to the tomb, and one step from the tomb to the palace. The house of the dead was, probably, in all instances, as well as those of royal and illustrious personages, meant to be a shadow of the living. The tomb of Psammis, opened by Belzoni, or rather of Petamon, as we read the Phonetic characters of the royal inmate's name, supplies no doubt a good image of the interior chambers, staircases, communications and accommodations of a royal palace, or of the hotel of a Theban Magnate. Of the house of the merchant and tradesman we have an extant model. Among the most curious of the memorials of the new Egyptian Room, British Museum, is the model of an Egyptian dwelling in "hundred-gated Thebes," which was, as Homer calls her, the "proud mistress" of the world. It is on the left hand side in case K 2. It had probably been a child's doll house, but the representation is not the less accurate and curious on that account. It appears to be the dwelling of a corn-factor. The model is an oblong of 2 feet in length by 18 inches in width; the walls are 5 inches in height, and the door, which is near the angle of the side, is 4 inches in height by 2 in width. We see, in its simple construction, the model of all the private houses in the East up to the present time. It is the model, on a smaller scale, of Homer's palace of Ulysses, in Ithaca. It is the model of the old-fashioned inns in this country, which were originally constructed like

the caravanserais of the East. A high wall, without windows, conceals the mansion from the street. It is entered by a portal, which appears almost similar to the doorways let into similar dead walls in Cairo at the present day (as described by Captain Lane). The rude wooden bolt by which it is fastened, passing, when shut, nearly across the entire door, appears to be an improvement on that of Ulysses, who merely used a cord and a knot to fasten the royal bedchamber door. The door opens into an interior court, at the end of which are warehouses of corn, the windows of which are closed by similar wooden bolts. A staircase ascends from the court to a gallery, which had two chambers above, one without, and the other with, a roof; the first probably being the sleeping, the latter the dwelling apartment of the mansion. It is probable that the defensive arms and valuables of the family were kept here, as they were in an analogous situation in the palace of Ulysses. In order to complete this sketch of the domestic architecture of Egypt, one example (the only one extant) of a royal or lordly mansion, intermediate between the merchant's dwelling and the temple palace of the pontiff kings, exists in the Banqueting Palace or Pavilion (as it is called in the French great work "*D'Egypte*") at Gourm. It has two floors, the upper exhibiting the only instance of windows in the Egyptian style, harmonizing with the sloping doorways. The lintels of the windows are ornamented with the zigzag mouldings, and the imposts are elegantly enriched with the globe and winged serpents. A balcony has been supported by caryatide heads of conquered people. The front elevation is handsomely crowned with a semicircularly crenated parapet. The whole, if restored, would make a striking front for a mansion or Regent-street shop. It has had two projecting wings, forming, with the *corps de logis*—(like Buckingham Palace and the Louvre)—a quadrangle which may have been completed by a palisade or propylon,—the origin of the triumphal arch. The interior decoration is light and graceful, unlike the usual severity of the Egyptian style.

The ordinary model of Egyptian temples and palaces was grandly simple, but extremely monotonous. Nothing could be more uniform. Two obelisks first, and then two seated statues, sometimes two androphynxes, usually preceded a gateway, permeating two turrets constructed in the form of flat truncated pyramids. The gateway gave access into a quadrangle, the covered cloisters of which were usually supported by pilasters and caryatides. At the extremity of this quadrangle another gateway lead into a second colonnaded court; the gigantic face of the colonnade, facing the entrance, constituted the open portico of the temple. Sometimes the judgment hall, as at Luxore and Karnac, supported by larger and loftier columns than those of the portico, succeeded. Then followed the Pronaos, and six smaller chambers and Sekoi, as it might happen, all roofed and dark, sometimes supported by caryatide pillars and sometimes not, and uniformly terminating in a rectangular isolated small chamber, which was the "holy of holies," and usually contained either the monolithic cage of the sacred animal worshipped within the temple, or the sculptured and seated forms of the three-fold divinity, which presided over the sacred edifice.

This was the ordinary form of the principal temples, including the ecclesiastical palaces of the pontiff kings. In the more ancient temples generally sculptured from rocks, as well as those of districts which were more limited in expense, the gorgeous accessories to which we have referred, such as avenues of sphynxes, obelisks, statues, colonnaded courts, many pillared porticos, and judgment halls, were retrenched, and the temple assumed the more primitive character of a double columned portico, and three rock-hewn chambers, the pronaos, the naos, and the holy of holies.

We shall find, as we examine the most ancient temples of Egypt, which stud the two rocky sides of the Nile with magnificent relics, from the southern confines of Nubia to the cataracts of Philæ, that the general description we have given of the ecclesiastical monuments of Egypt, applies, with slight variations, through the whole series, to one prevailing and unvarying archetype.

Thus the ground plan of the great palace of Luxore resembles, though far short of it in colossal dimensions, the ground plan of the

astounding temple and palace of Karnac. It is clear, from history and extant relics, that the same analogy is assignable to the almost obliterated palace built by the celebrated Memnon.

Let us glance at the most authentic accounts of the modern ruins of the Memnonium, in order to carry out our example. The two seated and broken statues, both ascribed to Memnon, but one identified with his vocal statue by the inscriptions on the leg, now the most conspicuous objects on the great plain of Thebes, preceded the gateway. They may have been preceded by an avenue of sphynxes, and succeeded by obelisks. They are at a considerable distance from the first gateway, and front the Nile, but they are in perfect line with the entire direction of the remaining ruins. "Within the first court, close to the pyramidal gateway, is a large colossal statue," says Pocock, "broken off about the middle of the trunk." The head of this statue was brought, after much labour, to England by Belzoni, and is now in the British Museum. Here it has obtained the name, though fallaciously, of the younger Memnon. "In the second court," says the same author, continuing his description, "are the remains of two colossal statues sitting, of black granite, the head of one of which is three feet five inches long." This second court of caryatide columns, a third court follows, in which are the remains of two seated colossi of black marble, one of which is also in the British Museum. A fourth court succeeded, which is not characterised by any remarkable remains. This court was probably, in its integral state, surrounded by a colonnade, as that portion of it which fronts the entrance, and which formed the portico, remains. The portico is primitively simple but sublimely impressive in its character. It consists of pillars of the oldest style of architecture, resembling those of Elephanta, in India, having large gourd-shaped capitals instead of cushions, which, in the latter case, appear compressed by the encumbent architrave. This leads into the pronaos, roofed and supported by gigantic columns, much loftier than the preceding, and having bell-shaped capitals. Another portico, with similar capitals and columns, follows, and most likely, like the preceding, formed one side of another quadrangular court, being the fifth, and at this the ruins end. It is probable that a considerable number of courts, porticos, *sekoi*, may have occupied the intervening space between this part of the ruins and the excavated tombs of the kings. Judging from the line of direction which the series of ruins take, and from the analogy of the sepulchral Palace of Osymandes, this would seem to be the case. Let us now see whether there be any probability in the supposition that Diodorus Siculus, in describing from Hecateus the sepulchral Palace of Ismenides, described in fact the Memnonium. Norden and Pocock show themselves to be decidedly against this opinion, by searching for the remains of the temple of Osymandes at Luxore, on the eastern bank of the Nile; for Diodorus Siculus gives the account from Hecateus, after describing the other sepulchres of the Theban kings, which are notoriously on the western bank, and not far from the Memnonium. It is true that they discover paintings in Luxore similar to those which Diodorus Siculus describes as being in the palace of Osymandes. But it is not probable that the pictorial narrative of such exploits should be confined to one locality. Indeed, similar representations are found at Ipsambul. The real fact is, (and considering the vicinity of the royal tombs, it goes far to establish the identity of the Memnonium with the sepulchral palace of Osymandes,) that the very pictorial sculptures referred to by the historian, are seen at this day in the Memnonium. The modern ruins, too, correspond with the description of Diodorus. First there are entrance courts, after passing the usual entrance gate between two towers (truncated pyramids). After this there was a colonnaded quadrangle, supported by "animals after the antique manner," says the historian, and as, indeed, is observable in the temples of India and Japan to this day. The roof of this quadrangle was "spangled with stars on a sky-coloured ground," as in "Belzoni's tomb," as at Denderah, and other extant palaces and temples. Another unadorned court followed. In this were three statues, all of one stone, erected by or for "Memnon the Syenite." One of these was the largest in Egypt, and was in a sitting posture. The first exceeded seven cubits in length. The other two, which were not so large, were

placed at his knees, one on the right, and the other on the left. This was the famous statue of Osymandes, on which the boastful inscription, "I am Osymandes, King of Kings," was written. This has been supposed to have been the vocal statue of Memnon, the word *Ismendes* meaning to *give a sound*. That this, however, is not the broken column of the plain is quite clear. It is accompanied by another, and neither are so large as the one described. There can scarcely be a doubt, however, that this is the statue described by Norden as broken in the middle, and lying in the entrance of the second court of the Memnonium. The size precisely agrees. It was 42 cubits or 63 feet high, and the foot described as 7 cubits in length lies there at this day, and was seen successively by Belzoni, Capt. Light, Leigh and other travellers. It can scarcely be doubted, therefore, that the sepulchral palace of Osymandes was the Memnonium. After this court there followed another colonnaded quadrangle, "of more note than the first." In this was portrayed all the King's wars against the Bactrians. Upon the first wall the King was represented storming the wall of a city surrounded by a river, and fighting in the front of the battle against his enemies, with a lion by his side, and making terrible slaughter." This battlepiece, perfectly concurring in every particular with the historian's description, has been copied by Champollion. "On the second wall the King was represented leading his captives." This was also copied by Champollion. "The captives were engraved without hands, to indicate their unmanly character." This representation is also given by Rosellini and by Champollion, the King being seated in a car, a pile of hands before him, and the captives (Bactrians, probably, by their costume, with plaited locks, beards, and striped tunics open in front) waiting the operation of the executioner. "The third wall represented the King offering sacrifices and celebrating his triumph." This historical picture, in all its elaborate details, is copied by Rosellini and Champollion. The proof, therefore, may be regarded as curiously established, that the Memnonium was the sepulchral palace of Osymandes. "On the fourth wall, says the historian, two statues were placed sitting, each 27 cubits in length." These are clearly the same as those described by Norden in the second court, that which follows the caryatide court. "Two sitting colossal statues of black granite, the head of one of them 3 feet 5 inches long.

"Near to these," says Diodorus, "three passages led out of the colonnade into a hall supported by pillars into a musical theatre. This agrees with the Covered Hall (the Hypostyle Hall at Karnac is built in the same manner) supported by columns which still remain, and which was faced on both sides by a colonnaded court, the pillars of which are lower, and of different capitals from those which support the hall. This appears to have been the judgment hall or court of the 40 monarchs or judges, where they held their sessions, and where the thirty days general assemblies of the people were also in all probability convened. Norden, speaking of its decorations, says, that "they surpass in strength and beauty every thing he had seen in al fresco or mosaic work;" and that "the gold, ultramarine, and other colours employed had preserved their lustre unimpaired."

The chief variety in the forms of the columns has been described. Were the five orders known to the Egyptian architects? The negative must be admitted. The Doric alone can be claimed by the Egyptian architects, as borrowed by their Greek colonists and pupils. Rosellini settles this point by exhibiting the Doric column and entablature in the portico of the tomb (containing the tableau of Joseph and his brethren) at Beni Hassan. However, the elements of the capitals of the four remaining orders may be detected among the colonnades and porticos of the Egyptian temples. The germ of the Ionian volute and capital (both derived from a female face and its ornaments) may be seen at Dendirch and Philæ.

It has been remarked that the pillars of the Hypostyle Hall at Karnac are Saxon in their waved ornament, bell-shaped capital, and sturdy cylindric shaft. Many of the capitals employed by the monastic architects (see the multiform capitals in the "Temple Church," by Robert Billings) are strikingly like the exuberant variety of graceful forms, derived from trees, flowers, tendrils, or creeping plants adopted

by the architects of Egypt, and forming the first *elements* of the Corinthian and composite orders.

It is true that there is a deficiency in the portico of Doric columns at Beni Hassan. But if the metopes and triglyphs appertaining to the perfect Doric style be wanting, oval metopes (adopted as mysterious emblems under the name of *vesica piscis*, by the monastic architects of the earliest Christian eras, alternating with triglyphs,

are found on the entablatures of the most ancient rock-hewn temples of Nubia, also at Esueh; while Denderah exhibits a more elaborate metope, alternating with pentaglyphs,

which consists of a Shekinah, or golden flood of light descending on an ark from between two cherubic serpents (the Urim and Thummim), whose wings are stretched over the ark.

The ground plan of the temples supplies curious matter for remark. As our architects adopt the Christian cross +, so the architects of Egypt adopted the Tau

or three limbed cross of Hermes, indication of future life. This ground plan may be traced equally in the palace, the temple detached or troglodyte, and the tomb. The ground plan of the tombs of Lycopolis consists of a series of *taus* mysteriously, as in the freemason's royal arch,

united. The *tau* and *square* united, form the elements of the most elegant of the scrolls called Greek, and borrowed from the Egyptians. In the temples and palaces of New Spain, the Christian cross is adopted for a ground plan, and such a cross is sculptured in the *sacellum* of Palenque. But the Palmer's cross was familiar to the Egyptians,

and often seen in the hands of Horus, the second person of the Trinity. United with the symbol God.

It meant Saviour God. Sir G. Wilkinson says that the Christian Cenobites identified the Egyptian cross with the Christian, and adopted it as a predictive mystery and symbol in their own ritual. It appears among the sculptures of their chapels. It by no means follows, therefore, that the cruciform ground plan of the tombs and temples of New Spain proves the conversion of the builders to Christianity. Both the tau and cross were among the most ancient sacred symbols of Egypt.

The ground plan of Luxore, and the series of obelisks, statues, gateways, and sekoi, so entirely resemble the ground plan and model of the Memnonium, which Champollion ascribes to Rameses, the father of Sesostris, instead of to Memnon, while he assigns Luxore to Sesostris as the Sesostreum, that the description of the one may almost pass for the description of the other. Karnac, built by successive kings of the same dynasty, exhibits all the peculiarities of the same original ground plan and design in its most highly developed and ambitious character. It may justly bear competition with the troglodyte temple and palace of Ipsambul, which was built by Sesostris, and offers favourable means for comparison between the two styles; that of the detached and that of the rock-hewn temple and palace. We have said before, that the rock-hewn temples and palaces occupy both sides of the valley of the Nile, from Meroe to Syene. The modern localities may be named in succession, Ibrim, Deir, Amada, Sebou, Derri, Garsery, Dukey, Offadooneh, Ipsambul.

The whole series may be described under one category. This holds good as far as regards the larger number of the series of temples, sculptured from the living rock. In a few instances, as at Garsery, Dukey and Offadooneh, the rock-hewn temple is preceded by propyla, seated statues and sphynxes. In all the instances, the portico of the temple, the naos, pronaos, and holy place are cut from the living rock. There is scarcely any difference in the model. The 4 or 6 cubic pilasters which, in the primitive temples, support the pronaos, in the more elaborate shadows, as at Sebou and Ipsambul, are examples by gigantic caryatides.)

The great work of the late Champollion "*Monuments de l'Egypte et de la Nubie*," published, as it will be seen from the title, by a special commission appointed by the French government, under the distinguished auspices of M. Guizot, the present premier of France, and his late colleague, M. Thiers, when minister of public instruction—contains, in its recent number, illustrations of the great architectural monuments of Egypt, when architecture was in the most "high and palmy state" of the 18th dynasty. It is devoted to Ipsambul; but the numbers comprise details of the two structures erected by Sesostris at that place, the Speos of Athor, the goddess Venus, and the Speos, or Sesostreum, cut out of the solid rock, and apparently consecrated to the combined purposes of temple, palace, and tomb. In the temple or Speos of Athor, there is nothing which calls for prolonged commentary. The founder's favourite wife, whom Champollion calls Nofreari, is represented throughout as the presiding divinity of the temple of Venus; in one case apotheosized and worshipped by Sesostris in the character of Athor; in the other associated with him in the presumptuous claim of divinity, he being enthroned by her side in the character of Ammon. Part of a dilapidated statue of Athor appears on the extreme walls of the sacellum of the temple. The figure has a cow's head surmounted by a lotus, and the name Athor, which signifies House or womb of the Sun, the Egyptian Messiah, or Bethshe-mish, threatened by the prophet "with having a fire lighted in it, which should destroy its images," is clearly visible above the head of the broken and decayed statue. Marks of fire are met with throughout the interior. The antithesis implied by the prophecy between the real fire threatened and the profane fire lighted up within this temple by the orgies of Venus, and the presumptuous dedications of mortal beauties which cover its walls, is obvious and striking. The eighth and ninth folios of the first livraison represent the front elevation of the great Speos of Ipsambul, which, indeed, depicts and records the Titanian ambition of its great founder.

Four of the Caryatides which support the architrave are enormous colossal statues of Sesostris himself, and two of his favourite wife, in the character of Venus or Athor. At the foot of each of his statues stand

two of the princes, his sons, and at the foot of each of her's, two of the princesses, her daughters. But the latter do not rise above half the height of the leg of the six colossi which compose the magnificent and unique portico of this astonishing troglodyte palace. On the left side of the portal, Sesostris is sculptured in the act of slaying a vanquished negro, who wears large gold earrings; on the right side he is represented in final conflict with the same chief of the nation of the Robou, whose duel with him is depicted at Luxore. The gigantic character of this *façade* may be appreciated by a glance at the large head lately built up over the doorway of the Gallery of Antiquities, British Museum, which was cast by Mr. C. Smith, from one of the fallen Caryatides. The resemblance of Sesostris to Napoleon is remarkable.

It is our opinion that the Egyptian style might be applied to new buildings of a particular class, as well as to street architecture. We recommend it as being preferable in many respects to Greek, Palladian, or Gothic. We do so looking at it with a view to saving, to applicability, and to capacity. This noble and impressive style of architecture has been too much neglected in this country, although it has been adopted with great advantage in some of the chief cities in the American Union. That it is the incorporation of the sublime and beautiful in architecture no one can deny. But it is also capable of as great elegance, harmony, and beauty as the pure Greek style, by which we mean, not the Roman Greek adopted in our street and sacred architecture, and represented in its high state of improvement by the *chef d'œuvres* of Michael Angelo and Sir C. Wren, but the pure Greek style distinguished by its peculiar characteristics of the barn shaped cella, portico and peristyle. The Egyptian style, in its severer characteristics, is equally well calculated for churches and for palaces, for lordly mansions and for prisons. Again, nothing can be better calculated for cemeteries, piers, lighthouses and quays. It has the special merit of being eminently economical. With regard to ecclesiastical architecture, the lantern spire of those churches which have been lately built on the Greek model, is an invention of modern times, as a substitute for the towers and belfries of the Gothic sacred edifices. In some cases it has been well adapted, in others badly; as in the instances of the Lantern of Demosthenes, the Temple of the Winds, and the Choragic Monument. Although there be no instance, except the single example of the pavilion we have noticed, of two stories being employed in the Egyptian sacred or palatial structures, and no instance of the addition of a turret or spire, yet it is our opinion that an addition of this description, in conformity with the Egyptian style, might be rendered applicable both to palaces and churches. A steeple supplied to the flat roof of the Egyptian *pronaos* in the form of an obelisk or pyramid would, we apprehend, be a failure; and in proof of this we need look no further than the steeple of All Soul's, in Langham Place, and the pyramidal spire of St. George's, Bloomsbury. But architectural ingenuity would conquer the difficulty; and it must be recollected that the imposing *façade* of an Egyptian temple was in all cases grandly associated with lofty towers of truncated pyramids; towers which, beyond a question, originated the belfries of the Eastern Christian churches, and the minarets of the Turkish mosque.

These few concluding suggestions are neither uninteresting nor unimportant at the present time, when a city of palaces has succeeded, as if by magic, a congregation of narrow and squalid streets. The result is in every respect good, whether we look to mere gratification, or to the improvement, by the diffusion of good models, of the public taste, so intimately connected with the arts of design, on which our manufacturing prosperity depends.

E. C.

THE EASTERN PENITENTIARY OF THE STATE OF PENNSYLVANIA.

(Designed and executed by JOHN HAVILAND, Esq., Architect.)

THIS admirable specimen of prison architecture is situated in the North-western environs of Philadelphia, about two miles from the centre of the city,

it occupies an elevated site near the river Schuylkill, and presents one of the noblest, and most commanding architectural objects in the country. It was commenced in the year 1822, and completed in 1837, at an expense of 600,000 dollars.

The principal front is 670 feet in length, and is wholly composed of finely wrought granite, accurately jointed, and employed in unusually large masses.

The character of the composition is strikingly appropriate to the objects of the building; its bold and massy features, its broad lights and deep shadows, its well proportioned and well managed openings, and the expressive unity of design which characterizes the whole, produce on the mind of the spectator a most solemn and impressive effect.

The entire *façade* is *castellated*, and its embellishments are in the "early pointed," or "lancet" style of English Gothic. The gate of entrance, which occupies the centre of the front, is 15 feet wide by 27 feet high; the upper portion of it is secured with a massive wrought iron port-cullis, and the lower part with immense oaken gates, studded with projecting iron rivets; the jambs of the opening are strengthened by massy buttresses, which at the same time, impart a bold architectural effect to the composition.

On either side of the entrance a square tower is constructed, of 50 feet in height, crowned with an embattled parapet, supported by pointed arches springing from corbels. These towers define the extent of the centre building, which is about 200 feet, and their projection from the face of the main wall is 10 feet. The curtain between the towers is also embattled, and its height from the ground is 41 feet.

The extremities of the front are finished with octagonal towers pierced with loop-holes and pointed windows, and crowned with embattled parapets; and a massy octagonal tower rises out of the centre of the front to the height of 80 feet, thus forming a picturesque termination to the group.

The outside walls are 30 feet in height, 12 feet thick at the base, and 640 feet in length on each side, thus enclosing a space equal to about *ten* acres.

The cells are built in *seven* blocks or ranges, radiating from seven sides of an octagonal building of 40 feet in diameter, situated in the centre of the enclosure. The cells of each block are built on either side of a spacious corridor, and these corridors all lead to the centre building, thus affording a view of every cell door in the whole establishment from one and the same point of sight. The upper part of the centre building constitutes an observatory, from which a complete supervision may be had over the entire enclosure; and the lower part, or cellar, contains a reservoir for supplying the establishment with water.

The whole number of separate cells contained in the *seven* ranges, amounts to 844. The three blocks which were first erected are but one story in height, and to each cell is attached a separate yard of 18 feet long by 8 feet wide, surrounded by a wall of 12 feet in height: these enclosures were intended as airing yards for the prisoners, but it has been found, by experience, that the ample dimensions of the cells, and their perfect ventilation, render it unnecessary to remove the prisoners *at any time* from their cells, except in case of sickness; hence, in the four ranges which were subsequently erected, the yards have been omitted, and the cells made two stories in height. The second stories are approached by means of galleries extending along the corridors, supported by cast iron brackets; the stairs, and the balustrading on the galleries are also composed of cast iron.

The cells of the different blocks, or ranges, differ in dimensions, the smallest being 11 feet 9 inches long by 7 feet 6 inches wide, and the largest, 14 feet 9 inches long by 9 feet wide. Each cell has a separate hydrant, a water closet, an aperture for admitting pure air, and a flue for ventilation.

The whole prison is warmed on Perkins' plan of hot water circulation through iron pipes, and those who have the management of the institution seem to be satisfied that the plan is a good one for such an establishment.

The front building, through which the prison is entered, contains, on the right of the gate-way, commodious apartments for the Warden, and chambers for the meetings of the Inspectors. On the left are the clerks' offices, and the rooms of the deputy keepers. Over the entrance, on the second floor, are the apothecary's apartments, and in the left wing, the infirmary.

A high degree of architectural taste and skill is evinced in the whole design of this noble and costly structure, while the beauty and solidity of its execution are equally creditable to its accomplished and tasteful architect, John Haviland, Esq., whose name it is destined to transmit with honour and renown to after ages.—*Franklin Journal*.

ON DREDGING BARS OF RIVERS.

BY A. C. JONES, ENGINEER.

Having seen in the American newspapers several projects for deepening the water, or removing the bars at the passes of the Mississippi river, I am induced to give a sketch of what was done by the United States steam dredger *Balize*, as I am firmly convinced that the only feasible plan for improving the passes is by dredging. First removing all the lumps in the ship channel, and then deepening the bar by carrying it away as raised. It is idle to talk of damming, ploughing, or dragging, as these projects would never enter the brain of any person that was conversant with the difficulties to be encountered.

An impression exists that the bars consist of soft mud, and are easily removed. This is erroneous, for the bars are hard, and studded with mud lumps, which are forced by some subterranean agency through the bottom, and up sometimes as high as ten feet above the surface of the water. These lumps consist of a compact clay (alumine,) of the consistence of cheese, and the surface receives a fine polish when cut with a sharp knife. The action of the water has very little effect on the lumps, (some have perpendicular sides,) except during severe storms, when the tops are washed off to the surface of the water. When the surface is slightly inclined, it is generally covered with innumerable clay pebbles, the fragments of the lumps taking that form by the action of waves on them.

For a perfect understanding, I will give a short history of the Dredger from her commencement. The boat was built by John Vaughan, at Kensington, in a substantial manner, and the engine and dredge machinery, by Messrs. Levi Morris and Co.;* all being fair specimens of Philadelphia workmanship. The whole being under the immediate direction of Captain Andrew Talcott, United States corps of Engineers. The machinery for one side being so far completed as to make a partial trial in the dock; all bidding fair to perform well. The boat was hurried off in the early part of January, 1838, before the full completion of her machinery, through fear of being detained by ice. The *Balize* did not prove to be a good sea boat, owing to the peculiar distribution of the machinery on board, and in consequence of the roughness of the sea, caused considerable rolling; the boilers being cylindrical, and on the guards, at times, it was difficult to keep the water at the proper height. I found great benefit in knowing the level of the water, by the use of my gauge tube, as described in the Journal; the ordinary gauge cocks giving incorrect results, especially when foaming. The boat drawing nearly two feet more water than her proper draught, made the passage long.

I may mention here that I found the carbonate of lime in the boilers increase in quantity, in a given time, as we proceeded South, although the precaution of cleansing the boilers at the stopping places, and constant blowing, was strictly attended to during the voyage.

On the arrival of the boat at the North East pass, it, and all the force, was put in requisition to assist the corps of engineers in the survey which was then going on; and it was late in the season before all the necessary fixtures were completed to commence dredging. After several trials, it was found that the chain being part of cast iron, (although proved to a strain of twenty-seven tons, at Philadelphia,) frequently broke, owing to the hardness of the bottom, coupled with the great size of the buckets, the contents of each being one cubic yard. New chains were immediately ordered, but owing to shipwreck, and other causes, the chain for one side, although first made, did not arrive until eight months after. On the receipt of chains for one side, numerous experiments were tried at different parts of the bar, perfecting the machinery, and drilling the men. In November, orders were received to proceed with the dredger to Red river, to remove a bar at the mouth of the Chute—prior to our arrival, the pent up water had cut a channel of sufficient depth. The only obstacle was an island of mud, 140 feet long, and 50 feet at its greatest breadth; the whole being two feet above the surface of the water. The dredger was moored alongside, and operated on it with the buckets of one side, and in 23 working hours, one-half of the island was removed down to 13 feet water. As the particles of mud were only carried away by the current, the same mud was raised by the buckets several times, and as many of them came up heaped, so as to contain two cubic yards, it

was computed that the dredge raised the enormous quantity of 600 cubic yards per hour,† which is far surpassing any other machine in the world.

The *Balize* then removed back to her station, at the North East Pass, and proceeded to cut away a mud island, or lump, standing in the centre of the main channel, at the mouth of the Pass. The weather being stormy, the sea forced us to abandon the lump, after making several partial days work on it, and we then operated at the head of the bar proper, which extends five-eighths of a mile from the sea; this enabled us to work in smoother water. The bar being formed of alternate strata of sand and deposit from the river, making the bottom hard; and as the buckets were designed for soft mud, their size prevented their acting well—but with this disadvantage, 1500 cubic yards have been conveyed away by the hoppers, without extra exertions, in eight hours working.

On the 5th of March, we again moored alongside of the island which we previously worked on, and commenced working actively at it, when the sea would permit. The subduing it was necessarily a slow operation, its size being about 350 feet by 150, at its greatest breadth; the top being almost at the surface of the water, with nearly perpendicular sides. The dredge was a long time cutting at it with the buckets of one side before any mud could be raised by those of the other side, to be conveyed away by the hoppers.

On the 5th of April we had cut and removed nearly half of the lump down to 13 feet water, the boat was then shifted to the north side of it, and on the 12th the dredger (drawing 8 feet water) passed over the top of the lump, operating with both sides and filling two hoppers at the same time.

On the 17th of April, 1839, orders were received to stop dredging and lay the fleet up, the appropriation being expended. A few thousand dollars more would have removed this lump from the channel, as the smoothness of the sea at this season of the year admitted of nearly constant working—subsequently the fleet was ordered to Mobile and there laid up.

The principal difficulties encountered in our operations were, 1st, in placing the machinery from the want of correct knowledge of the bottom—for although several partial surveys had been made by different persons from 1820 down, and inquiries from shipmasters and others supposed to be conversant with the actual state of the bars, yet their reports left the impression that the north east bar was soft mud and easily removed; as this proved to be incorrect, the consequence was that numerous alterations had to be made as experience pointed out.

2nd. The operations being on the margin of the Gulf of Mexico, great loss of time was experienced from the prevalence of easterly gales, which blowing against the current of the river caused considerable sea, the depth of cutting being from 13 to 15 feet, the force of the sea had a great effect in deranging the machinery.

3rd. In conveying the mud away from the dredger often considerable time was lost by the hoppers not discharging their load (100 cubic yards) owing to the mass becoming compact.

A great loss of working time was also owing to the tow boat frequently getting aground and blundering in bringing the receiving vessels to, and taking them from, the dredger, all these, coupled with the general inexperience attending works of this kind and magnitude, and being distant over 100 miles from the nearest workshops, prevented a successful beginning; but the latter part of the operation, owing to the perfection arising from practice, was highly successful, and will bear a comparison with any other dredging operation.

In connexion with the foregoing, I give you the mean of a number of experiments made with the engine at Mobile, during the month of June, 1839, these may be relied on as correct, although differing from some of the theoretical properties of expansion. I was unable to give higher speeds to the wheels on account of bringing home the anchors, the boat being moored in the stream.

The horizontal cylinder is 19½ inches in diameter, and 7 feet stroke, and works either by a whole stroke eccentric or a ½ cam, the exhaust either way being the whole stroke. Each wheel is of the double form, 18 feet 7 inches in diameter; extreme length of the bucket 6 feet 10 inches; each section has 12 buckets 21 inches deep.

The shaft has two fly wheels and couplings to admit of the engine being worked independent of the wheels.

The time for experimenting was chosen when there was little or no current, the engine being in perfect order, and working with little friction.

* As a proof of the excellence of the workmanship of the engine, I will give one example. When I left the boat, the key of the connecting rod, at the cross head end, remained as driven when steam was first applied to the engine, it not having been required to alter it.

† That there may be no doubt of this, I will state that eight buckets were raised per minute.

8 × 1 × 60 = 480 cubic yards, even measure. The buckets being kept heaped, 600 yards is a safe estimate.

One pair of boilers were used, these being on the guard made the length of the steam pipe about 13 feet, it and the cylinder being covered so as to lessen the radiation of heat. At the time of the experiments the boat had a list to port, which made the immersion of the starboard buckets two and a half inches, and the larboard ones seven inches. The pressure in the boilers being one and a half pounds to the square inch, the throttle valve being open (during the experiments,) and the whole stroke on, just kept the engine in motion, being equal to the friction.

Pressure in the boiler, lb. per square inch.	Steam as applied.	Revolutions per minute.	Remarks.
6	Cam.	7.5	Engine alone
6	Eccentric.	18.5	
5	Cam.	None.	
5	Eccentric.	12	Starboard wheel coupled. Larboard. Both wheels.
4.4	"	Just move.

10.4	"	"	"
13.5	"	3.3	
20.4	Cam.	Just move.	
24.4	"	6	"
24.4	Eccentric.	9.5	"

I also verified the experiments noted in this journal, to prove that the water displaced by steamboat wheels did not come from before them. I strewed the surface of the water with chaff and then set the wheels in motion, and found that six inches in front of the wheels the chaff floated undisturbed.—*Franklin Journal.*

EXPLOSION OF A STEAM BOILER AT MANCHESTER.

In the beginning of the month of October last, an awful occurrence took place through the bursting of the boiler of a steam engine, at the factory of Messrs. Elce & Cottam, in Jersey Street, Manchester, which occasioned the death of nine individuals working at the factory. An inquest was held upon the bodies before James Chapman, Esq., the coroner for the borough of Manchester, who has very kindly furnished us with a copy of the depositions, from which we now extract the most important part: the inquest was held on the 14th day of October last, and was adjourned until the 5th day of November, for the purpose of allowing competent parties to examine into the cause of the accident.

Steward Sands was examined. He stated that he is a pattern maker, and had much experience in the working of steam engines, and has been in the employ of Messrs. Elce and Cottam for the last nine months. The engine was a six horse power high pressure engine, and was an old one; the boiler was cylindrical, with *egged* (flat) ends of wrought iron, three eighths of an inch in thickness, and stayed from end to end by an iron rod passing through it, and cottered at each end. He thought the boiler had been overweighted from the quantity of machinery the engine had to move. The engine had not started, as he was going into the yard, to any work; but the safety valve attached to the boiler would be weighted for the machinery it had to put in motion during the day; this was too much, and caused it to burst. On the first floor there were two grinding stones, seven lathes, a drilling machine, a smith's bellows, and a boring apparatus for head stocks. On the second floor were one small grinding stone, six lathes, a planing machine four feet long, a centreing machine, and a wheel-cutting machine. In the third floor there was a roving or jack frame containing 72 spindles. With the exception of the centring machine, all had been at work up to six o'clock the previous afternoon, and had been turned by the engine. The roving frame, which started about a fortnight ago, worked only at intervals. It had been at work the day before the accident from three in the afternoon until six, and it was intended to be worked with the others the following day. The boiler was 3ft. 6in. in diameter, but he could not speak to its length, and was in good condition and well calculated to work an engine of six horse power, but no more. The cylinder was eight inch bore, and two feet stroke. For this engine thirty pounds to the square inch was sufficient, and from the quantity of turning that had to be done, he thought the engine was overworked. It would take three or four horses power more to perform the work the engine had to do. When the engine is not overweighted, it goes so freely that its motion is not heard, but when it is overweighted it goes stiffly, and makes a loud hissing noise. He perceived, for the last three months, by those signs, that the engine was overweighted. He thinks it will take two horses power to drive the jack

frame. He knew Edward Allen, the late foreman. He is quite sure the engine and boiler were overweighted by about three or four horses power the evening before the accident. Yesterday, about half past three in the afternoon, I told Mr. Elce that the engine had been overworked; he said he thought not before the jack frame had been put on. Sands said "You must know it was overweighted;" and Mr. Elce replied, it was not overweighted, but he thought the jackframe was more than what it was calculated to work.

John Lee, of Manchester, machine maker, was examined. He stated that he had much experience in engines and boilers. Saw the premises immediately after the accident, and since the boiler was found, and has examined it and the ruins, in order to ascertain the cause of the accident. He first thought that the boiler had been short of water, and that by pumping cold water upon the heated plates, it had generated some elastic force very suddenly, so as to cause explosion; but on enquiry, he found that the engine had not started that morning. Boilers oftener burst at starting than afterwards. If there was too much steam in the boiler, or if it was overloaded, if the pressure had been gradually generated, and the valve was not fast, danger would not ensue; but if suddenly generated, or the valve fast, explosion would take place: the valve was of sufficient size to carry off the steam in case of over pressure. He thought from the first that the valve was not fast, because the first projectile force was given through the safety valve, which threw the blowpipe across the two yards, a distance of 160 feet, and forced the same six inches into the brick embankment, and from an examination of the valve since, he was of the same opinion. He found the valve in good order, but the valve rod was bent in consequence of being thrown from the boiler at the time of the explosion. He got the rod straightened, took off the gland, and found inside a greasy substance, and the packing was in good order. From this he concluded that the valve had not been neglected. He thinks the boiler was sufficiently strong, the plates being thicker than those he had seen in boilers for a similar purpose. His opinion is that the stay rod was not sufficient to counteract any sudden expansion of the steam, but it is such as is generally made and in use at the present time. It would have been better had there been more stay rods. He thought the link to which it had been attached to the back end, being the one first found, was defective, the same having been bent the wrong way of the iron; had it been bent the right way, it is possible the explosion would not have taken place; the shell of the boiler he conceives to be as good now as when it first came out of the maker's hands. He was of opinion that the plates had never been red hot. It was not possible for explosion to have taken place in case of the plates becoming red hot, unless (?) cold water had been poured upon them, which could not have been the case in this instance, as the pump had not been worked that morning, the engine not having started. He could not speak with certainty whether, if there had not been sufficient water in the boiler, and the boiler had become heated, the effect upon the water would be such as to create explosion before the safety valve could be acted upon. It is the opinion of some that decomposition of water in a close vessel by heat creates hydrogen, but that could not explode without an admixture of oxygen, and not even then until it was ignited: were it possible for this effect to take place, all the safety valves that could be affixed could not have prevented explosion. He could not risk an opinion as to what has been the cause of the explosion in this case; it must have been from sudden expansion, but how originating he could not tell. If such explosion had taken place at the stopping of the engine instead of the starting, he should not have felt so much astonished, as engines are repeatedly stopped when the steam is up at the full pressure, which must throw the elastic force instantaneously into the boiler; but in doing this, he has never known explosion to take place. He does not think there is more danger in high pressure than in low pressure boilers, provided they are properly attended to, because, from observation, he conceives that the majority of explosions have been from low pressure boilers. He does not think that any additional valve was necessary in this case, but a second valve is certainly better. He has frequently been on Messrs. Elce & Co.'s premises, and from what he has seen, and their general mode of conducting business, he does not think there is any blame attributable to them. He has measured the boiler. It is 3ft. 11in. in diameter by 9ft. 6in. long, being round, and having flat ends, and was capable of working from 7 to 8 horses power. The apparatus attached for indicating the pressure were, a safety valve at the top, with a lever attached to a Salter's balance, which indicated the pressure per inch by figures engraved on the face of it, and a glass gauge in front indicating the height of the steam (water?) but these, except the safety valve, he has not seen as they were destroyed by the explosion; there were also two pipes with taps at the ends inserted at the top of the boiler, the one for steam, the other for water; if the boiler was short of water, the latter so being opened would allow the steam to escape, which would be a sufficient indication that the boiler wanted water. He thinks these, if in good order, were quite sufficient, and from inquiries he has made, they were in good order. If cold water had been thrown in amongst the steam whilst the water was boiling, the boiler would have collapsed. There is no such appearance about it now. If upon the plates when hot, it would create expansion (? contraction)—there were no such appearances

INSTRUCTION IN DESIGN, AND SCHOOLS IN THE SEVENTEENTH AND EIGHTEENTH CENTURY.

GREAT as the outcry has been of late with regard to schools of design, the plan is by no means new to the metropolis. At the latter end of the seventeenth century, while what we may call the mechanical portion of art was still flourishing, the symptoms of decay were apparent; and a little later, the general introduction of composition ornaments caused a rapid decline. The foundation of the school of drawing in Christ's Hospital is perhaps the first instance of the recognition of design as an essential part of useful education; and it is surprising that it had not a more extensive influence. About the commencement of the eighteenth century, when Strype published his edition of Stow's Survey, the overthrow of the lower branches of art may be considered as complete; and we find Mr. B. Lens exerting himself to produce a better state of affairs. His arguments, published by Strype, are quite identical with those which have been lately urged; and it will perhaps afford some gratification to extract at length Strype's account of his school. (vol. I. p. 173.)

"Another school for drawing, limning, and painting, set up anno 1677, by one Mr. B. Lens, now or late living in Fleet-street, an art exceedingly useful for all sorts of people, as for gentlemen that travel, * * and for tradesmen; such as are concerned in building, as masons, carpenters, joiners, painters, and the like. The professor of this art teacheth on Tuesdays, Thursdays, and Saturdays, in the morning from 8 to 11, and on Mondays, Wednesdays, and Fridays, in the evening, from 6 to 9; the price, a guinea entrance, and a guinea a month. * * He hath very well set forth the general usefulness of this art by a printed paper, which may deserve to be here inserted. *Graphice*, by Aristotle is generally taken for the art of drawing anything (*Γραφικε*) whatsoever, with the pen or pencil, and was reckoned among the chiefest of those his *παιδεύματα*, or generous practices of youth, as rendering them so many ways serviceable to their country, and profitable to themselves. Of incredible service and advantage it would be to our smiths of all sorts, masons, bricklayers, carpenters, joiners, carvers, turners, embroiderers, tapestry-workers, silversmiths, jewellers, nay, to all our handicrafts in general. For, show most of the workmen abovesaid a draught of what you would have done, their want of skill in drawing renders it almost useless to them. For example, should an engineer invent a machine, and draw it in all its parts, with its views per front and sides, the whole in perspective, a ground-plot thereof, with a scale annexed thereto; with what difficulty do they work, and the projector must be always by, or all will be marred: whereas, could our handicrafts and mechanics draw, a man might send his work from a hundred miles' distance, drawn as abovesaid, and be satisfied it would be performed to his mind, and according to his directions. By what has been said, I would not have it thought that none of our handicrafts and mechanics can draw, for some do, of my knowledge, very well; which qualification hath made them the most excellent of all others, for the best draughtsman will be the best artist, in what art soever. The design of this school is to have a constant nursery or breed of youths proper for artificers. * * For proof of what hath been said, discourse with the meanest of all our handicrafts, though he cannot draw, yet will endeavour to chalk out, after his fashion, your meaning and his; knowing by pure instinct, that all the rhetoric in the world cannot convince like a drawing. * * If parents sent their children to drawing, as customarily they do to Latin and writing, it being altogether as useful to them, they would soon find the advantage themselves, and their children would reap thereby; for a master would take a servant qualified with drawing with half the money, and be a gainer thereby, for the boy would come to work in half the time." * *

That Mr. Lens's intention was a good one, there can be no doubt; but whether in making a charge of twelve guineas a year he made his school acceptable to the working classes, admits of great question. As being a labourer in the cause of public instruction, he is, nevertheless, entitled to much praise, although the time was so unfavourable to a successful issue of his attempt. Mr. Lens was also a private teacher, and afterwards became drawing master in Christ's Hospital.

OBSERVATIONS UPON THE COMPARATIVE ADVANTAGES AND INCONVENIENCES OF THE EMPLOYMENT OF IRON WIRE, OR BAR IRON, IN THE CONSTRUCTION OF SUSPENSION BRIDGES OF GREAT SPAN.

By M. LE BLANC, Chief Engineer of Bridges and Roads.

(Translated from the French.)*

CABLES of iron wire, and chains composed of bars of wrought iron, may be compared with reference to their economy and their durability.

As regards economy, the question scarcely deserves discussion, and it is easy to prove *à priori* that, in all possible cases, iron wire has the advantage over wrought iron.

In fact, the Council of the *Ponts et Chaussées* has adopted the principle, that cables of iron wire should be submitted to a tension of 12 kilogrammes (26½ lb.) per square millimetre (·0016 square inches) of section; but for bar iron, it was decided that the maximum of tension shall not exceed 8 kilogrammes (17·6 lb. nearly).

This principle is founded upon the comparative resistances of iron wire, No. 18, ordinarily employed in the construction of cables, and of iron bars 3 to 6 centimetres (1·2 to 2·4 inches) in diameter.

The natural consequence of this principle is, that the section of a chain should be greater by one half than that of a cable, for the same tension; this involves a proportional increase of its weight. In cables of iron wire no joints are used, or at most, but a single one, as in the bridge of Argentat, and this joint made up of two small eyes, weighs but little—on the contrary, they are numerous in chains, and where the system is rather complicated, as I shall prove it should be in bridges of great span, each one of these joints weighs at least 140 kilogrammes (309 lb.). On the supposition that the suspension rods are 1·2 metre apart (47½ inches), as there is a joint for each rod, there will be 233 kilogrammes (514 lb. nearly) for a bridge of 180 metres (590 ft.) span. This additional weight, together with that of the bars themselves, which, as we have just seen, is one half greater than that of the cables, produces an excess of tension which must again be resisted, whence there arises a new increase of section, and consequently of weight in the chains. In applying these principles to individual cases, it is found that the weight of the unit of length of a system of chains exceeds double that of a system of cables.† Now, as the price of iron wire is once and a half that of bar iron, it is plain that the use of iron wire is more economical than that of wrought iron.

I have proved that the total tension is much greater when chains are used, it follows that greater strength must be given to the moorings and to the intermediate piers, when the bridges have several openings or bays—a new cause of increase of expense.‡

It appears to us to have been thus thoroughly proved, that in regard to economy, the cables of iron wire are superior to chains of wrought iron.

Let us now compare the two systems in relation to their durability.

The principal objections which have been made to the employment of iron wires are the following:

1st. They offer greater chances for rapid oxidation.

2nd. The imperfection of the present process for manufacturing the cables does not allow us to give an equal tension to all the wires, so that when the cables are raised to their places, the wires which are under most tension have to support many pounds in excess—while those under least tension do not draw at all.

* We are indebted for the translation to the American Railroad Journal.—EDITOR.

† In the comparative proposals which I presented for the bridge of Roche Bernard, I showed that these weights are in the proportion of 11 to 25; in order to replace 11 kilogrammes (24 lb.) of iron wire, which at 1f. 50c. cost 16 francs, 50 cen., we must employ 25 kilogrammes (55 lb.) of wrought iron with 25 francs.

‡ In bridges of several bays the cables or chains should be fixed to the intermediate piers, in order to avoid the great changes of form which result from unequal loads upon the two bays, if the chains and cables can slide freely over the top of the piers. Because these piers have to resist only the difference of the tractions produced by different additional loads upon the two bays, it would appear at first sight a matter of indifference whether the permanent loads which are in equilibrio are greater or less; nevertheless it is plain that the less these permanent loads are, the better the piers are in condition to resist the maximum load of one bay, the other being destroyed: it is, then, not unimportant that we diminish the permanent load as much as possible.

3rd. Cables form a system less rigid than chains of wrought iron do, so that the horizontal oscillations of the roadway are more considerable in the former than in the latter case.

I believe that I have not withheld any of the objections urged against the employment of iron wire, nor weakened those I have presented. I shall now examine them in order.

First objection.—They offer a much greater chance for oxidation.

It is certain that if we expose to alternations of dryness and humidity a bar of iron and a certain number of isolated wires, the sum total of their individual sections being equal to that of the bar, the surface attacked will be far greater in the wires, and in them the oxidation will be most rapid.

In confining ourselves to this general *fact*, without reference to any of the means employed by art for retarding this oxidation, it will be well to examine if even this inconvenience of the more rapid destruction of the cables, is not more than counterbalanced by the advantages which they present.

It is very evident that if the cables remain only forty years without being renewed, while the chains may last for sixty or one hundred years, we must calculate what will be the amount at the end of forty years of the sum saved by the use of iron wire instead of bar iron.

To render this more plain, I will give an example. I suppose that a given suspension bridge requires 200,000 kilogrammes (441,096 lb.) of iron, (which was nearly the quantity for the bridge of Roche Bernard).

The expense of the system of suspensions	300,000 francs.
According to note (1) to replace the iron wire there must be used 454,545 kilogrammes of wrought iron, which would cost	454,545

Saving in favour of iron wire,	154,545 francs.
--------------------------------	-----------------

Now this sum put at interest, will amount at the end of twenty-three years, to 475,506 francs, and supposing that the cables must be entirely renewed at this time, there will still remain a surplus of 175,596 francs, which will be more than sufficient to produce at the end of another twenty-three years, a new capital equal to the cost of the system of suspension.

In the case which we have considered, cables of iron wire lasting but twenty-three years will then be preferable to chains of indefinite duration.

The supposition that isolated wires will last twenty-three years without the necessity of being renewed, is not without foundation—and we shall produce a fact which strongly tends to confirm it.

M. Mongolfier, jun., having learned that a grating of iron wire from the church of St. Martin's at Paris was about being taken down, after having remained forty years without any repair, had the curiosity to prove these wires, after having carefully ascertained their number, and he was convinced that they had lost but one-fifth of their entire strength.*

This loss of strength is not sufficient to require a complete renewal of the system of cables.

But the most determined opponents of the use of iron wire confess that cables do not afford such facilities for oxidation as detached wires. The greasy substance which covers them affords a powerful preventive to rust; their union preserves them in the interior, more or less, from moist air; the ligatures are a still further obstacle to its introduction; and finally, the careful superintendence which should be given, are all reasonable motives for hoping that the effects of oxidation may be diminished in a remarkable manner.

It may be objected that experience has not fully confirmed the opinion, however probable it may be, that cables are less susceptible of the attacks of oxidation than iron wires. I confess that no one fact can as yet, incontrovertibly, prove the justice of this opinion, but there are several which we can produce, capable of giving much strength to it.

The bridge of Tournon has been in existence eleven years, but no very considerable trace of oxidation has manifested itself, at least, to my observation, upon the surface of the cables; and if there existed any in the interior, it would not have failed to show itself by a brownish stain upon the outside of the paint which covers them.

A bridge of iron wire was built at Brest, in 1526; the cables, exposed to the salt air, which attacks iron with so much energy, should have undergone a remarkable deterioration in the space of three years. M. Trotte de la Roche, Chief Engineer, who, on account of the plans adopted for the port, was obliged to dismount it, took the pains, at the invitation of M. Inspector

* The increase of oxidation is not as rapid as would be supposed from the first observations made—for the first layer of rust which covers the surface of a bar of iron, instead of favouring this oxidation, proves a coating which is an obstacle to it.

General Lamblardie, to prepare a *process verbal* of the state in which he found the cables.

It appears from the *process verbal*, 1st. That the continuous ligature which covered the cables was slightly attacked, but that by the first scratch of the file, the oxidized portion was removed. 2nd. That the exterior wires of the cables showed slight traces of oxidation, but that the slightest scratch of the file caused them to disappear. (M. Trotte de la Roche supposes that the oxide was only deposited upon the wires of the cables, and that it came from the ligatures.) 3rd. That the interior wires were perfectly untouched.

Eight years is a short space of time, but if we consider that the effects of oxidation probably continue to decrease, we may conclude that they are not so very rapid, and that the fears entertained upon this point are greatly exaggerated.

An observation has been made, which is worthy of remark; it is, that in chains the surface of the bars which is attacked by oxidation proves the portion of them offering the most resistance, while in a cable the interior portions have the same strength with the others.

Second objection.—The imperfection of the present process for manufacturing the cables does not allow of an equal tension in all of the wires, so that when the cable is raised to its place, the wires under most tension are overstrained by many pounds, while those under the least tension do not draw at all.

This last objection is a serious one, and cannot be absolutely done away with, that is to say, it is impossible to prove that this defect does not deserve the most serious attention; but we can employ, in defence of iron wire negative arguments, or in other words we can prove that it is not possible to resolve the problem of equal tension in a more perfect manner by the system of chains than by that of cables of iron wire.

We must, in the first place, distinguish carefully between bridges of large or small span; in the latter, where the tension requires only a section of the chains equal to that of 4 to 8 bars of about 0.05 metres to 0.06 m. (2 to 2½ in.) in diameter,* (dimensions beyond which the quality of the iron becomes considerably deteriorated,) we can establish on each side of the bridge two or four separate chains in one or two layers, each chain being made of a single bar only; in these two cases the problem of equal tension is perfectly resolved, and although in the second each suspension rod bears upon two chains which cannot have exactly the same curvature, the holding plate of the rods will always bear upon the two chains, which will then support equally their share of the whole weight of the bridge.

By establishing three or even four layers, we can form an excellent system of 16 chains, each made of a single bar; but these 16 chains present only a total section of less than 44,000 millimetres (97,041 lb.), corresponding to a tension of 352,000 kilogrammes, (776,329 lb.) that is to say, to bridges of medium span; but if we pass to bridges of such a span that the tension increases to more than a million of kilogrammes, it will be necessary that the chains should be composed of 48 or even 64 bars, that is, 24 or even 32 bars on each side.

Let us consider the last hypothesis, which applies to the case of the bridge of Roche Bernard.

It is impossible to employ the simple system of suspension rods resting upon a couple of chains, of single bars, and arranged in layers, for we would then have 16 of these layers, one above the other, which, beside the inconvenience presented by a considerable height, would allow of the attachment of suspension rods only at every sixteen intervals upon the same chain.

Here then it is necessary to employ a more complicated system, namely to form the chains of several bars fastened together by a single bolt—in this case I would reduce the number of chains to eight, and form them of eight bars, fastened by one bolt.

We can double the number of chains, and so reduce to four the bars in each, by making each rod rest, by means of plates, upon two chains at once, but if the two chains forming the couple are not in the same plane, the upper plate of the rods will bear only upon one of the chains—for it must remain parallel to the plane of the four bars—and one half of the system will support nothing; this disposition is too faulty to be adopted—this is my opinion in the hypothesis of eight bars to each chain and fastened by one bolt.

Whatever may be the manner of forming the eye at the end of the bar,

* I reason on the supposition of the use of round iron, of which I need not prove the superiority over square iron, that is hammered again after being re-heated to a cherry red.

† I suppose it would not be desirable to employ more than four layers—this number is already considerable and troublesome in the passage over the towers and in the moorings.

either by welding it to the end itself, or by bending over a portion of the bar, it appears to me very difficult to prevent differences in length of at least a millimetre between the bars.

Now if there is this difference between bars, 5 metres (16·4 feet) in length, the shortest must lengthen a millimetre, or ·0002 of their length before the others draw.

But we know that a tension of two kilogrammes per square millimetre of section produces upon a bar an elongation of ·0002 of its length.

The bars then of which we are now speaking, are strained to the amount of 4 kilogrammes (9 lb.) (per sq. millimetre) before those beside them suffer any tension; what will this amount to if the differences in length are more than one millimetre?

We see then that the problem of equal tension is as difficult of resolution for a complicated system of chains as for iron cables, for supposing that in the two systems, the excess of tension, either of one wire over another, or of one bar over another, is the same, this excess will be a much smaller fraction of the absolute strength of wire than of bar iron; moreover, the manufacture of cables affords a greater hope of perfection than that of chains.*

We see now that the second objection has no more weight than the first, to decide us in favour of wrought iron chains.

On the other hand, there are objections against the employment of bar iron more difficult to remove, and which will give additional strength to the reasons which have induced me to yield the preference to iron cables.

Those objections are as follow:

1st. The greater part of chain bridges which have fallen have given way at the bolts which unite the links. Now it is extremely difficult to calculate the strength which should be given to them, as we do not perfectly understand the manner in which they resist the strain; if we compare them to bars placed upon fixed bearing points, and charged with a weight in the middle, and the resistance of which is derived from a formula $P = M \frac{a b^2}{2 c}$

we find the dimensions very small, too small indeed, according to many experiments.

If we suppose them to resist as if drawn in the direction of their length, (and many constructors admit this hypothesis,) we arrive at large sections, which greatly increase the weight of the joint; besides this, we have no certain information as to the quality of the iron which they need; it should not be so soft as that of the chains, because no curvature is required; but still it should not be brittle. To avoid mistakes prejudicial to the durability of the work, it is wise to make them rather too strong than too weak; but as I have just said, an increase of weight is the consequence of this precaution.

2nd. The making of the eye requires great attention; it has been observed, that when the bolt is too little, during the proof, a rent takes place from the outside to the inside of the head of the eye; when the bolt is too large, the rent opens from the inside toward the outside. Now, as it is almost impossible that the work of man should be perfect, in order to avoid the inconvenience above-mentioned, several constructors have proposed to swell out the head of the eye, in order to give it greater strength; but to do this we must re-disturb the particles of iron by hammering after having heated it, an operation which I have already designated as faulty.

3rd. During the oscillatory motions, which take place in all suspension bridges, the irons rub forcibly against each other at all the joints, and this tends to wear them in those parts which have the greatest strain. This inconvenience does not exist in wire cables.

4th. In the moorings we are compelled to use curved irons, which have of course been re-heated, and are most often squared; this new heating, and the difficulty of proving them, obliges us to give a greater size, which involves another increase of expense.

5th. In very cold weather iron becomes brittle; wire enveloped in grease,

* To make the bars as equal as possible, we can indeed, after having bent and welded the ends, drill through all of them which make up a link of the chain, when cold; but it is evident in this case, that to prevent the drilling from diminishing the strength of the eye, we must either give greater size to the bar in this part or flatten it, involving a heating which injures the quality of the iron.

† There are, for instance, some red shear (hot short) irons which lose nothing by being wrought at a white heat, but which are injured in quality when wrought at a less elevated temperature. But the workmen cannot confine themselves to fulfil these conditions exactly, whence it happens, in irons which have even been proved, that the re-forged portions become bad, and consequently, that only the final proof can give evidence of this imperfection; but as we have just said, it is very difficult to prove curved bars.

and not in immediate contact with the air, must be less brittle than naked bars of iron.

6th. Cables in bridges of great span, can be much more easily raised to their places than chains. In the proposal for the bridge of Roche Bernard, I have calculated that the weight of a cable would be 7,968 kilogrammes (17,673 lb.), while each chain would weigh 31,496 (69,462 lb.); a work equally difficult, it may be said, has been executed at the Menai bridge; but if this proves that it is not impossible, it does not prove that it is not very difficult.

M. Vicat has asserted, that wires before breaking, suffer a considerable elongation, which announces the rupture beforehand, and thus gives time to make the necessary repairs, while chains break instantaneously.

This advantage of iron wire has been disputed, in the case of wires united in bundles by ligatures, and the interstices of which are filled by grease. M. Frinot thinks that these bundles form a brittle system; he doubtless would like to say, as brittle as bar iron. In support of his opinion he has cited the *herse*, a sort of skein of hempen thread, which has most strength when its elements are free, and loses part of it as soon as the loose threads are bound together, and approximated to the condition of ropes. If this assertion is confirmed by experiments—and I have prepared some for this purpose—cables will in this point of view, be neither worse nor better than bar iron.*

Third objection.—Cables form a less rigid system than bars of wrought iron, so that the horizontal vibrations of the roadway are much greater in the former than in the latter.

For equal curves and weights this is true, but when we have once given the preference, even in point of durability, to wire over bar iron, (and I confess I have done so,) will we not gain more by increasing the rigidity, by means of the greater weight of heavier timbers for the roadway, and by diminishing the curvature of the cables, or the tension which they should bear per square millimetre of section, than by substituting chains for cables?

These latter likewise admit of an arrangement which cannot be adopted for chains. I refer to the cradle form; and in this case the outside cables being in a plane, inclined from the vertical, have a tendency to draw the whole roadway towards them, and as this takes place on both sides, it follows that the roadway is kept in its position better than it would be by means of stays.

I offer these reflections to the readers of the *Annales*, as the result of perfect conviction in my own mind, after deliberate consideration, and I can indulge the hope that this conviction will be shared by at least a small number of my associates. I shall examine in a subsequent article the advantages and inconveniences of a diminution of curvature, and the defects in the proof which chains and cables undergo, either before or after being placed.

Suggestion for the Prevention of Fire in Churches.—A correspondent of *The Times*, remarking upon the frequent occurrence of fires in churches, as well as other old buildings, in which the modern practice of warming by stoves has been introduced in buildings not originally constructed for that purpose, suggests that if the plan were adopted in all new churches, and in such of the old as are capable of it, of sinking a well near the great western door of the church, and fixing a forcing pump thereto, to the spout of which a short hose might be adopted, and which might also be so contrived as to fit the hose of the parish engine, and be under the care of the sexton, many very destructive fires might be prevented by the timely application of water thus easily supplied on the spot, as in most cases where a fire occurs it is small at first breaking out, and a few buckets well applied would be sufficient to extinguish it; while, as is well known, from the extreme difficulty which now occurs in procuring water at these generally isolated buildings, the fire has made an alarming progress before any supply of water can be made available. In some places, the rain water from the roof might be conducted into a tank, which would answer the purpose equally well, and also be made very useful when repairs are being made, and for the purposes of ablution, now so much neglected, from the absence of water in the churchyard.

* M. Lauraut recently attended to the work of the bridge of Roche Bernard, and has given me some details in regard to the *herse*, which can explain the objection of M. Frinot. The *herse* is made by laying the threads in a circle, and if they are perfectly parallel and evenly stretched, the inside ones are shorter than those outside; if ligatures are applied, and the *herse* is drawn out, as it must be to lift or pull loads, we see that the threads of the bundle, which from being circular are now straight, or even bent in opposite directions—the outside threads then must be thrust up together, while the inner ones, if they do not stretch, must break. Without the ligatures there would be a compensation between this lengthening and shortening, so that they actually injure the strength of the bundle; but it is the change of form, and not the ligature, which is the cause of the evil, and the *herse*, bound or not bound, would have the same strength, if it retained its primitive form, as is the case with cables of wire.

LEVELLING.

SIR—At page 434 of your journal, I have just read W. Bewley's remarks on the subject of attaining the correct bisection of a levelling staff; and although I cannot agree with his plan of "the holder moving it slowly and firmly to and fro, in the plane of the observer, the base of the staff acting in its seat as a hinge," because I believe, by such means that the base of the staff would in some degree work itself into the ground (except an universal joint was attached to the foot), which, if at a back station, would occasion a certain error; probably of much greater amount than would be occasioned by a reading from the staff when in an oblique position. The principle of adopting the *least* reading on the staff is of course correct, and is really well worth the attention of every person engaged in levelling operations. But I have always found, that with the most careful holder, and on a calm day, the inevitable unsteadiness of hand was sufficient to enable one to practise this plan with certainty. In windy weather, the vibration of the staff always ensures the same result, constantly passing and repassing the perpendicular. In conclusion, Sir, allow me to state, that in my opinion, the *simple* plan detailed in W. Bewley's letter is well worthy of your readers' attention; and there is the reproach conveyed in the postscript to W. Stevenson's letter, at page 26 of your last number, unmerited.

Charlotte-street, Bloomsbury,
Jan. 13, 1842.

I remain, Sir,
Your obedient servant,
PETER BRUFF.

LONG AND SHORT STEAM VOYAGES.

SIR—A correspondent Z in your last number appears to lean to the opinion of Dr. Lardner respecting the profit to be derived from long and short voyages by steam. I think, however, he is not borne out by the examples adduced. With respect to the list of transatlantic killed and wounded, mentioned by him, it is necessary to say a few words in explanation.

"Sirius withdrawn."—The Sirius was a small vessel, and was never intended to be kept permanently on the transatlantic station. She was chartered for a voyage or two by the company owning the British Queen and President, while their ships were building, and though sailing from an Irish port, was, I believe, the most unprofitable of all, and the soonest withdrawn. "The Royal William"—was also a small vessel, chartered by another company until their own vessels were ready.

"Great Liverpool transferred." The Liverpool was certainly unsuccessful. This arose partly from the circumstance of her return on the first voyage after being out some days, which created an unfavourable impression against her, and being an indifferent sea-boat, she never attracted many passengers. She has since been altered by giving her six feet more beam, and is now, I believe, a very superior vessel.

"United States or Oriental transferred."—She was intended for the station, but never made a voyage.

"British Queen sold." The British Queen made an average profit on nine voyages of £1256 per voyage; and before the opposition of the Cunard line, which is assisted by a Government contract, considerably more.

"The President lost."—The President made an average profit of £1350 per voyage while she ran. These two ships belonged to the same company, and would have paid a handsome dividend on their cost, had it not been for the Cunard* opposition, and the unfortunate loss of the President, which was insured for a fourth part of her value only. She therefore took to the bottom with her the £60,000 of the company's capital mentioned by Z, and swamped her owners.

"Great Western and Great Iron Steamer for sale."—I am unable to say whether these are for sale or no. The Company have some disputes whether they shall build their own ships or not; and as the courts have decided against them, their building-yard is advertised for sale. The Great Western has regularly divided nine per cent. on her cost, besides laying by a considerable reserve fund; so she can scarce be quoted as a proof of non-success with long voyages. Your correspondent says that a "recent meeting of the Peninsular and Oriental Company enables us to state, that oriental steam

voyaging has been highly successful; and this result has been attained with the same vessels, and by the same management, that were incapable of realizing anything but loss on the New York line." That the vessels are under the same management, is entirely a mistake; that they pay a good dividend (seven per cent), is quite true. But how? The Company's capital is £300,000, and they receive from Government £66,000 for conveying the mails to Lisbon, Gibraltar, and Alexandria. It is evident that without this Government assistance, the Company's vessels, with their short voyages, would not be dividing £21,000 a year among the proprietors, but would, as Z says, be still realizing a most considerable loss. I think therefore, from what I have said respecting the Great Western and these latter vessels, it will appear, that the length of the voyage is of far less consequence than the probability of a full ship to make it with.

I have the honour to be, Sir,
Your obedient servant,
AN AMATEUR.

MODEL MAPPING.

SIR—I have perused with considerable interest your report of Mr. Sopwith's paper on the construction and use of Geological Models, for which he was awarded a Telford medal by the Institution of Civil Engineers,—and I trust you will allow me to make a few remarks on the analogy his proposition bears to the one I have advanced in my little work of Model Mapping, in which I suggest, that in all cases where the owners of estates are desirous of informing themselves, of the material and undersoils, as well as the surface and contents of their lands, Model Maps should be extended in their usefulness, so far as to portray geological formation. The mode I propose is to sink shafts in the model correspondingly with the borings taken on the ground, and into these shafts to insert rods of the same length as the depth of the borings, coloured geologically, to vertical scale; each difference of colour agreeing precisely with the strata of subsoils, as reported by the borers. The rods would be made to fit neatly in the shafts, though easy of removal, and would assimilate in use to the Grocer's *Cheese-taster*, which, when withdrawn from the cheese, identifies its qualities. Of course, I would not be understood to feel otherwise than that Mr. S.'s method is superior for mining purposes, but as the one I suggest does not render a division of the model necessary, but conveys to the observer the pure information derived from the borings, I am induced to believe that landowners interested in geology, and not initiated in civil engineering, would prefer it, as the simplest and least troublesome method, were their attention turned to the matter.

I am, Sir,
Your obedient servant,
J. BAILEY DENTON.
9, Gray's Inn, December 14, 1841.

STUDY OF CIVIL ENGINEERING AND ARCHITECTURE.

SIR—Believing you are ever ready to give publicity to any suggestions which may have utility for their object, I beg to offer the following considerations, which, should you deem of sufficient importance to claim a place in your Journal, you will kindly insert. A very few years since there was no place in existence where the study of Civil Engineering or Architecture could be prosecuted as a separate science. The student designed for either of these professions was compelled to wander through an intricate maze, without guide or compass to direct him, and often, as is too well seen at the present time, entered upon his duties without having even laid the foundation of a scientific education. There have been some attempts of late to fill up this chasm in the educational establishments of this country, by instituting departments in several of the Colleges and Universities, where the attention of students is exclusively devoted to subjects in relation to these branches of study; as also by the foundation of the College for Civil Engineers. Now these have, I am aware, in part supplied this desideratum, but in part only. Who is it that derives any benefit from these existing Institutions? are they the few or the many? most undoubtedly those only who have money in plenty, and the greatest portion of their time to devote exclusively to the acquirement of knowledge. But there are still a considerable number who not having such advantages, enter prematurely into offices, and therefore engaged

* The Cunard opposition is stated to have reduced the passage money 20 per cent, and to have reduced the number of passengers from an average of 240 to an average of 165 per voyage.

throughout the day, cannot avail themselves of these opportunities, and are consequently left without the means of preparing themselves for such important callings. To what can be attributed the fact that in nine cases out of ten, pupils pass through the term of their article-ship without having advanced in any material point? merely, that they commence and continue almost wholly in ignorance of any principles, and unable to apply even those they do know. Now it appears to me possible to remedy this evil in a great measure by the establishment of some place where the evenings only would be set apart for the pursuit of the necessary qualifications, and unto which a library, museum, &c. might be attached, if practicable; thus affording to those so situated means of improvement which are at present not to be found. Could the attention of those in whose power it is to carry into effect so desirable an undertaking, be roused to a sense of its importance, that the subject might be fairly considered, there is little doubt but that the result would be beneficial.

I am, Sir,

Your's, respectfully,

A STUDENT.

December 15, 1841.

ON COMPETITION.

SIR—Your correspondents have descanted frequently and largely upon the abuses of competition, and I concur generally in their censures upon existing practices. Without attempting however to discuss the merits and demerits of the subject, I will give you a case which may furnish matter for further comments; inasmuch as I believe it is in a great measure, if not entirely original, in respect to the course adopted.

The Magistrates of Devonshire advertised for designs for a County Lunatic Asylum, offering a premium of £100, or the chance of being employed to erect the building. About 20 designs were submitted; and after the committee had repeatedly conned them over, they candidly acknowledged their inability, without assistance and advice, to enter sufficiently into the consideration of all the numerous details, so as to be able to form a satisfactory judgment of their comparative merits. Accordingly they called in the aid of Mr. Hardwick, to examine and report upon the designs, in order to furnish them with clear and tangible data upon which their judgment might be grounded.

Mr. Hardwick having so long held the appointment of architect to Bethlehem Hospital, was therefore peculiarly fitted for the task; and it appears that he adopted the following course.

In reporting upon the whole collection of plans, after some cursory remarks upon the greater portion of them, which he deemed not worthy of a detailed consideration, he selected seven or eight of the most eligible, and made a tabular analysis of their contents under nearly thirty different heads; by enumerating of their various parts, by calculating the small quantities superficial and cubical, and arranging them in juxta position. Thus presenting at one view a comparison of the whole in all the various relations that can be expressed by figures; accompanied also by remarks upon their comparative merits in other respects.

The result was very curious and interesting; as for example, taking only the cubical contents and cost, the calculations of the competitors were found to range from 1½d. to 6d. per foot!

No conclusive judgment was pronounced in favour of any particular plan, the selection being left entirely with the committee.

Now it may be worth the consideration of your correspondents, whether the course described is not desirable in order to arrive at a fair and judicious decision—and if so, is it in the power of any committee, however zealous and honourable, to fulfil such a task; or even if they had the ability, could they devote the necessary time for comparing, analysing, calculating, &c? Further, if they could, and would do so, is it not better to be done by a professional man, who is not only more competent, but also responsible for the advice he renders? Is not such an ordeal of the designs calculated to detect fallacy and delusion, and thus prevent an injudicious selection? and is it not at the same time a great check upon collusion and jobbing? for under such an arrangement few committee men will be so daring as to vote in defiance of the merits of the case, with the liability of their corruption or ignorance being so readily exposed.

F. B. A.

MR. VIGNOLES' LECTURES ON CIVIL ENGINEERING, AT THE LONDON UNIVERSITY COLLEGE.

[We are indebted to our cotemporary the "Mining Journal" for an abstract of Mr. Vignoles' very valuable lectures, now in the course of delivery at the London University College. They will be found to abound with information of the utmost importance, not only to the student, but also to the profession generally.]

ON ARTIFICIAL FOUNDATIONS.

Lecture I. 25th Nov. 1841. After offering some comments on engineering generally, the lecturer alluded in particular to that important portion where the skill of the engineer was most required—viz., foundations. After some instructive remarks upon the subject, he said that for the foundation of bridges a network of timber had been used, and was found to be very good so long as it was under water; but if it were liable to become dry, and exposed to the effects of the atmosphere, it was sure to fail. He recommended concrete as far superior to timber; he had seen concrete forced into a quicksand, and no weight could afterwards force it out. Brick earth and clay form excellent foundations—the whole of St. Paul's, except the north-east corner, was built upon such a foundation, of from four to five feet thick; at the north-east corner, the architect being afraid to trust to the ground, it being rather softer than the other parts, had the clay removed, and a well of from twenty to thirty feet square sunk to a depth of about forty feet, where the hard bed was found; he then raised a solid mass of masonry to within nine or ten feet of the surface—arches were turned, and the foundation finished at an enormous expense; whereas, a few cubic yards of concrete would have answered equally well, if not better. All must have noticed the hole that was filled up in laying the concrete foundation of the Royal Exchange; there a few cubic yards of concrete did the work more expeditiously, and as well as the ingenuity of the mason could have effected it; he alluded to some of the most remarkable instances of the prodigality of architects in laying foundations, as the Barrière de l'Etoile (a triumphal arch at Paris), where the cost of the foundation far exceeded the amount of surface work; and the viaduct of the Valley Floré, in which a mass of solid masonry, thirty feet thick, was erected, extending all across the valley. In these cases concrete would have answered the purpose equally well, and at an enormous reduction in expense. Mr. Vignoles stated that the leading principles he wished to impress upon the minds of the students were—extension of base and equality of surface. He then, at some length, explained the different foundations that had been used for bridge building, and mentioned particularly Ranger's patent for curing defects where foundations have given way—viz., by using hot water to concrete applied in boxes, the hot water causing the concrete to expand. This was applied to the foundation of the Custom House when it had given way in consequence of a failure in the piling, which rendered necessary the application of an artificial for a natural foundation. He then remarked upon the various methods now in vogue for keeping the piles of bridges dry while under repair, alluding to caissons, and Mr. Tierney Clark's method of putting in the foundation of the landing place at Gravesend by portable cofferdams. The Professor concluded his instructive lecture, stating his wish to popularise the knowledge of engineering as a means of benefiting the public at large.

LECTURE II. Wednesday, the 1st Dec., 1841.—In the first lecture Mr. Vignoles gave the general principles of the various descriptions of foundations; in the present he proceeded to illustrate those principles by diagrams. He stated, that if a good foundation were provided by nature, the subsequent operations were simple, the main point being to imitate nature as closely as possible. Where the soil was bad, considerable skill was required; for instance, in laying the foundation for the pier of a bridge, a wall, or a column, the first point was to give the base extensibility, in proportion as the natural soil was weak, so in equal proportion must the size of the base be increased—the pressure must also be equal; the soundness of the foundation not depending so much upon the amount of settlement as upon its equality. There were various ways of obtaining this—viz., by the use of concrete alone, or in conjunction with timber, timber alone, or stone, or brick. Having so much insisted upon the necessity of an uniformity, it must be supposed that no portion of the artificial soil should escape; where that was likely, *sheet piling* must be resorted to. He then, by means of diagrams, explained the nature of that method—it being by driving piles close together, all round the foundation; the piles being (say) four inches thick, and as long as might be necessary. This method entirely prevented the escape of the soil in any manner but in a vertical direction, and ensured an uniform sinking, however bad the natural soil might have been. He then alluded to a very large chim

ney, twenty-two feet square, where the natural soil was a shifting quicksand; concrete was put in in layers, until the bed was eight feet thick; on this was placed a layer of flag-stones, five feet square; eight days after the work was completed, the whole sunk eighteen inches, without the least deviation from the perpendicular. Other modes had been adopted, amongst which was the following:—A number of timber balks were laid across, and concrete placed in the spaces between; then filled up with bricks; timbers were laid in a cross direction, and the flat stones placed upon them. In this instance the wood was laid where no change of atmosphere could affect it. The nature and use of a coffer-dam was then explained, and the Professor, at some length, showed the danger of incautiously drawing the piles; the vacuity occasioned by their withdrawal being filled up by the surrounding matter, greatly injured the stability of the foundation. In making one of the London bridges, a great disfigurement had occurred in consequence of the incautious withdrawal of the piles, one side of the pier having sunk one foot. The modern plan to prevent such accidents was to have a double coffer-dam—the piles of the inner one being cut off, and the outer piles might be withdrawn without danger. In laying foundations, he supposed there was a layer of soft ground, of moderate depth, with a hard substrata; piles must be driven through the soft soil into the hard bed; a very slight depth would be sufficient, but still, in most cases, sheet piling would be necessary.

The Professor said that he was lately indebted to an officer of the Bengal Engineers for an account of a very ingenious method, almost universally practised in laying the foundations of bridges and temples in India. It would not answer here, labour being so dear; but there, where wood was very scarce, building materials in great plenty, and labour very cheap, it was the simplest and most effective that could be imagined. From the explanation, it appeared that the system was the same as piling, but, instead of using wood, small wells of brickwork were substituted. Take, for instance, the pier of a bridge; a small well of brickwork was constructed—say, six feet deep, seven feet in diameter, with a hole through it, three and a half feet in diameter; this is placed on the sandy bed where the foundation is to be made; a workman gets into it, and undermines the well from the inside, the earth being drawn up in buckets, additional layers are added to the top of the well until a sound bottom was reached; and the singularity was, that there was not one or two of these little wells, but hundreds, and, in certain cases, to a depth of fifty-five feet; arches were then thrown across, and the superstructure raised. When the foundation was in the bed of a river, the excavation went on by the workmen diving through the water to the bottom of the well, and working there until obliged to come to the surface for air; for instance, through ten feet of water in the river and to the extent of forty feet of water in the well—one of the most extraordinary instances of perseverance upon record. English engineers had somewhat abridged the labour by substituting an oblong square of fifteen feet by four feet, with two elliptical holes for the workmen, so that, instead of three wells of six feet, they get one of fifteen feet—the principle being precisely the same.

In France a number of bridges had been built where the water was not rapid, upon a very simple foundation; a framework of timber being made, furnished with short piles at the corner, and laid in the bed of the river, and the superstructure raised upon it by means of a wooden diving-bell. The *pier perdue* was another way, but could only be used in still water; a quantity of stones were thrown in until a foundation was obtained; where there was any current this foundation was sure to give way, as in Plymouth Breakwater and Kingston Harbour. He then alluded to the case of one of the London docks, where the wall, being made with too great a curve, from the want of pile sheeting, the soil gave way—the engineer adding fresh matter until the toe of the wall actually appeared (to the astonishment of all) above the surface on the other side. He then gave examples of several original methods of preparing for the formation of foundations in Italy and Ireland by means of baskets of stones, &c.

CONCRETE.

The Professor next explained the nature of concrete, and gave directions for its formation—viz., one part of lime, twice that quantity of sand, and twice as much broken stone, or gravel, as there was sand.

The goodness of the concrete depended upon the quality of the lime. In making concrete, it must be borne in mind that the materials were far more bulky separate than when mixed; for instance, to make a cubic yard of concrete, which contained twenty-seven cubic feet, it would be necessary to have thirty-four cubic feet of materials, besides the water. The three ingredients should be mixed dry, and the water added; in slaking, the concrete will expand about one-thirtieth in bulk.

The great expense of coffer-dams, and of piers generally, had lately

led to a very peculiar construction of bridges by piling only, as, for instance, in iron bridges, no masonry being used. The Professor stated, that he had built seven or eight bridges upon that system; the piles were driven in and the iron work erected upon the wood. It had been tried to substitute cast-iron for piles instead of wood, but they had not succeeded, the iron being very liable to break. He also alluded to a beautiful arrangement for fixing branches to piles by means of a sliding collar, but which it is impossible to explain without diagrams. A French work, above 200 years old, was produced, with some very curious engravings of the modes then in use for securing foundations, and which proved that we are using the same means at present, and that many of our so-called new processes were in use at that time. He then concluded by stating, that, at his next lecture, he should bring forward some more general rules respecting foundations, and after that proceed to consider the best method of securing slopes of earth, now so generally in use.

LECTURE 3. Wednesday, 8th Dec., 1841.—Mr. Vignoles explained that at his former lectures he had applied the term "concrete" too generally, and would now explain the difference between "*beton*" and "concrete." Beton was formed of the usual quantity of sand and gravel, broken stones, &c., but, instead of using the ordinary stone lime, hydraulic lime was applied. He then stated that beton is used exclusively under water, concrete only where water does not get in; beton never sets until it is under water, while concrete will not set except it is dry. The lime used for beton must be first slaked, while for concrete it slakes in the process of mixing. Beton sets best when let down gently in cases, and concrete when scattered from an eminence. Beton takes months to become hard, while concrete hardens in a few minutes. The both are in purport essentially the same—to form an artificial stone or rock—the one for works under water, and the other for those on land. He then alluded to the knowledge of the ancients of beton and concrete, and read extracts from the works of sundry authors, from Josephus to the present time, proving that assertion. The use of piles was also very ancient, the foundation of a brick pyramid in Egypt having been constructed on that principle. After impressing upon the minds of the students the great importance of a good foundation, and the efficacy of concrete for attaining that end, he concluded, by stating that his next lecture would be again on the subject of foundations, and after that he would proceed to lecture upon slopes of earth, and explain the causes of the late accidents upon the different railways, pointing out where the errors of judgment had occurred.

LECTURE 4. Wednesday, 15th Dec. 1841.—Mr. Vignoles commenced by explaining the mode in which piles were driven in, and produced a model of a pile-driving machine (from the museum of the college), by means of which he showed the method in which steam power was applied to that machine for expediting the work—stating, however, that, far from that application being a novelty, he had used it himself twelve or fourteen years ago.

ROCK FOUNDATIONS.

Having treated in his former lectures upon foundations in natural soils, or various kinds of artificial bases, he would now notice such as were of the composite order, being partly on rock, and partly requiring artificial means to render them sufficiently sound for the required purpose. It often happens that, in making a bridge, there may be rock on both sides of the river, and the first pier may rest upon rock, while the second and third may have an insecure foundation, in consequence of a "pot-hole" (as it is called) of sand unexpectedly being discovered in the very spot where these piers are to be erected; the only plan to get over this difficulty is to cut the edge of the hole in steps; sheet-pile it a short space from the wall of the hole, and fill up the intervening space between the piling and the hole with beton, or some other substance, and thus form a continuation of the rock itself. Difficulties also present themselves in solid rock foundations; for instance, in such an erection as that at the Devil's Bridge; the ravine over which the bridge is to be thrown may have been formed by the running of water—the strata, accordingly, runs with the usual inclination on both sides. If foundations for the piers of the bridge were not sunk deep enough into the rock, the press of the water filtering through the fissures of the strata have such force that, notwithstanding the resistance of the arch, he had known instances of the pier being actually pushed outwards. The only method of avoiding this was to sink the pier so low into the rocks, and, by means of steps, secure it so firmly, that the force of the water must break the pier—not force it outwards—before it could destroy the bridge. The Professor, before going into the question of rock foundations, begged to state, that, in these lectures, he only laid down the general principles of foundations; he could not go into the details of the business, and the circumstances of stone foundations were so varied, that it was only by a life of labour

and experience that the best method could be arrived at; he wished that each student should, in his private study, well consider, and, by reading, test the correctness of the principles which he laid down for their guidance. A whole year's lecture, repeated every day, would be no more than sufficient to draw the attention of the student to important points—the details could only be gained by practical experience. In preparing the foundation of lighthouses, the whole resources of the engineer must be called into action. A lighthouse must be built in such a manner that it must actually grow from the rock; there are instances where lighthouses have fallen in a body. He could mention one in Ireland, the foundation of which was a solid rock; he saw a party who witnessed its fall, and who informed him that it fell in a solid mass, tearing away a portion of the rock with it. The fault was, that the foundation was not sunk deep enough into the rock. He then alluded to the celebrated Pharos (of Pharos) of Alexander, which was justly reckoned one of the seven wonders of the world; it was built about 283 years B.C., and received its name from the island on which it was built; it was 550 feet high, and the base was 150 feet square, and could be seen at a distance of 40 English miles. Josephus, and many other authors, had given descriptions of it, which pretty well agreed; and what was most extraordinary, that the very same method of making the foundation was practised then as now. The stones were dovetailed together, dowed, and run with lead, so as to firmly secure them in their places. The cost of the building amounted to no less a sum than 200,000*l.* of our money, and it lasted above 16 centuries; no diminution in its height occurred until after a 1000 years from its erection, at which time about one-third of its height was wasted away by time, and it was only within about 400 years that the whole is supposed to have been destroyed, and that only by means of an earthquake. He then remarked, that it was very seldom that the name of an engineer was handed down for 2000 years, but all accounts agreed that Sosastros was the name of the engineer who erected this wonder of the world. The celebrated Corduan, or, as it is generally called, Cordovan Lighthouse, at the mouth of the Garron, is built upon the same principles as the Pharos; this lighthouse is, however, circular, but the masonry is not calculated for durability, it being built of freestone. The expense of this lighthouse was enormous, as must be supposed, when millions of francs were expended upon ornament, which was the more absurd, when it was considered that it stood upon a barren rock, in the middle of the sea. He could not help quoting a line of Pope—

'Tis only usefulness that sanctifies expense.

This is a sentiment that he wished to impress upon the minds of all his students, for it was a great fault of modern engineers to expend great sums upon ornament, which could be far better employed upon actual necessities. He then turned to the Eddystone Lighthouse, and related the histories and fates of the two lighthouses preceding the one now standing, which was erected by the genius of Smeaton, and strongly recommended his pupils to read the account published of that great work. The Eddystone rock is peculiarly interesting to the engineer; it is found first at about one mile deep in the ocean, and then rises gradually about one foot in ten, until it reaches near the level of the sea, when a sudden crop makes its appearance, and rises above surface. From the peculiar formation of this rock, there is always a heavy run upon it, which renders it so very dangerous. The learned Professor, after explaining at some length the process of the erection of this celebrated lighthouse, concluded his lecture.

ON EARTH WORK.

LECTURE 5. Wednesday, 22nd December, 1841.—The Professor commenced by stating that earthwork, taken in the present extended sense of the word, was but little known to the ancients. The gigantic operations in earthwork of modern times correspond with the viaducts of the ancients. Our earthwork may be confined to excavation, cutting, and embankment, or getting and filling, as ordinarily denominated by contractors. He then went through the whole process, giving the scientific and common names of each description of work. With respect to the works of the ancients, in the canal made by Cyrus, the Phœnicians were the only workmen who cut the canal with slopes—all the rest employed cut straight down, and, in consequence, the former stood, while the latter fell in. The River Po, in Italy, was a curious instance of embankment; this river is situated in a very flat country, and makes an annual deposit of a calcareous matter, which, hardening, raises the bed of the river in a slight degree every year. The ancient inhabitants, to prevent their country from being inundated, were obliged to raise a small embankment on each side of the river—perhaps two or three feet high—which, having served for some years the desired purpose, and the bed of the river having become higher from the deposit, the embankments required to have still more added to them, until, after the lapse of centuries, the bed of the river, from the

constant deposit of calcareous matter, and the consequent necessary additions to the embankments, to the height of thirty feet, is now several feet above the level of the surrounding country. This work looks like one of our modern gigantic works, but it bears no comparison to the labours of the present day, it being but a work performed from year to year, in small portions at a time, while ours have been formed at one operation. From all his researches, he, therefore, came to this conclusion, that, until late years, earthwork was but little known; he could make the same remark with respect to cutting. This work was first treated systematically by military engineers in fortifications on the continent after the invention of cannon; authors of that period lay down many curious rules for forming ramparts. Various useful calculations are given to determine the best mode of making the matter taken from the ditch exactly sufficient to form the rampart, in order that there should be none either to procure or carry away. The next is in the construction of canals; the same rules were followed as in the construction of ramparts. In road-making the same calculations were made; the whole aim of the engineer being to make the imaginary line, called the "balancing line," so perfect, that the earth removed from the eminences should fill up the hollows in the irregularities of the country through which the road was to be made. The cause of these fine calculations was the difficulty and expense of carrying away the superfluous earth to another place. The absence of great undertakings on the continent is attributable to the want of our modern appliances to get rid of the superabundant matter. In the contracts sent in by foreigners for works abroad, it is amusing to see the finical exactness with which the contractors calculate the expense of removing the first 100 yards, then the next 25 yards, and so on increasing until they get to 300 yards, beyond which the price is enormous. It is only within the last three years that they seemed to have the slightest idea of the plans in use in England for facilitating this work; it is certainly not more than 30 years ago that we commenced using the tramroad. First of all the only plan was to remove the earth in barrows, then the clumsy three-wheel cart was introduced, after that tramroads, and now edge-rails, with the application of a locomotive, so that 30 years has changed the load from 2½ cubic yards to nearly 100.

Before railroads came into general use, deep cuttings were executed, and one remarkable instance Telford has left behind him in the Birmingham Canal, which is remarkable for boldness of idea and success of execution. Near Market Drayton there is an embankment, begun 15 or 16 years ago, and which is as yet hardly finished, so great has been the slipping and so difficult the remedy. This work is a remarkable instance of combined bad effects of a bad mixture; the slopes have flatted down until nearly in the proportion of 14 to 1, and it is now more like a large hill than an embankment. There is an instance of a deep cutting, by Dodd, at the Highgate Archway; it was intended, first of all, to make a tunnel, but, from the constant slipping of the earth, it was obliged to be made into an open cutting. The present bold mode of cutting down large hills and filling up deep valleys, in the formation of railways, is due to George Stephenson, and in the construction of large cuttings and embankments for canals to Telford, whilst Dodd made the largest cuttings for roads. On the Holyhead-road the failure of the embankments and cuttings in the London clay will teach a good lesson to the young students. The point to be considered is, which, of masonry, aqueducts, tunnelling, embankments, or cuttings, would be the cheapest mode of doing the work proposed. At the present time earthwork is the cheapest, for modern practice has reduced it to a price per cubic yard. In the contracts for the Paris and Rouen Railway, the contracts sent in by the French engineers were invariably 3 or 4 times the amount of those sent in by English contractors—thus, notwithstanding the expense of transporting the workmen into France, the whole of that work is in the hands of Englishmen.

The engineer, to form a just calculation, must well study the character and mechanical properties of the soil and the necessary slopes. Experience alone can teach these points. There are many varieties of the London clay, which, when cut down to a certain depth, on exposure to the atmosphere are sure to slip; another cause is, the great haste with which the embankments, &c., are formed. When the water does not penetrate, this clay is very hard, but after exposure it melts away, like tallow, and the only remedy is to get rid of the water by draining. When a slip takes place, the toe of the embankment bulges forward; in the first instance, the surface should be well drained a short distance from the edge—the drain to be puddled, in order that the water should not penetrate; borings should be made horizontally and the water tapped; when expense and time are no objects, the whole should be cut in steps, and drained by means of wattles, so that, if a slip takes place, it is only partial. The force with which the toe of the embankment bulges out is such that a wall of masonry would

be of no use, as it would be pushed out; the most effectual preventive, or remedy, is wattling and bush drains. When time will allow, it is better to make the embankments in layers, and between each layer of earth putting in a course of brushwood, clippings of hedges, or wattlings. When embankments are obliged to be poured out hastily, allow them to take their natural slope, and if it slips let it remain, for however much it may be attempted to reduce it to its former shape, it will still again slip and regain its position. A good practice to provide against slips is to form a slight abutment of earth, a short distance from the toe of the slope, so that it should stay the slip if it takes place; this plan is more particularly available when the work is obliged to be erected on a natural slope—for instance, on the side of a hill. The Professor, then, for the information of the younger students, explained, by diagrams, the nature of slopes, and the meaning of the expression "two feet to one," &c., and concluded by recommending that, in forming slopes, the engineer should run some risk of slips, in order to save the great expense of removing more earth than is actually necessary—the cost of repairing these slips being but little in comparison. He likened the work to an insurance on life—the risk to be run being calculated upon by precedents. The principle is to get the greatest extent of work finished at the least possible expense, and many of the great slips that have taken place might have been prevented, or speedily cured, had the plans he laid down been better followed.

LECTURE 6. Wednesday, the 29th Dec. 1841.—Professor Vignoles stated that, before continuing the subject of earthworks, he wished to set right an erroneous impression with the public, in consequence of an expression he made use of at his last lecture; he had then recommended that "the engineer should run some risk of slips, in order to save the great expense of removing more earth than was actually necessary—the cost of repairing those slips being but trifling in comparison." He need not say that he so expressed himself, but it was always on the supposition that no risk was to be run where there was the remotest probability of danger. He mentioned this because of the circumstance of the slip on the Great Western Railway, which was attended with such fatal results, and happening only a few hours after he had made that statement. From all that had been stated, it appeared that the slip itself was but very inconsiderable; the cutting where it took place was 57 feet deep, the slope two to one, and the width of the road 40 feet; the slip took place about half way up the bank. A number of smaller slips had occurred, and tiles were used for draining instead of bushes, &c., to cure them—still the mode of curing them was the same as he advocated—by drainage. As he had before stated, the slip itself was very inconsiderable, but, by having nothing to check it, the earth fell upon the rails. A doubt seemed to exist whether the concussion produced in the air by the passing of the former train had not brought it down, for the accident happened in the interval between the passing of the two trains—the first one having proceeded uninjured, whilst the latter was attended with such fatal consequences. If the precaution had been taken, when it was first observed that a slip was likely to occur, to put up a fence of hurdles to check its advance to the rails, doubtless the accident would not have happened. The manner of the slip showed that it was caused solely by the infiltration of water, probably a considerable way back from the edge of the cutting, or, perhaps the water had found its way in by the ditch along the top; the water which had thus got into the soil having expanded during the frost, the sudden change of the weather brought down the earth. The Professor then, by means of a diagram, explained the nature of the cutting, from which it appeared that the "top lift" was deposited in spoil bank; at the top of the cutting a drain had also been cut, but he was of opinion that such drains were injurious, when the soil was at all precarious. The spoil bank was not the occasion of the slip, since it did not take place at the top, but bulged out in the middle. Although this slip was very small, from the fatal effects which attended it, it was the more necessary to guard against the recurrence of the like; there were but a few feet of earth on the rails, yet the effect was the same as if so many planks had been placed upon them. The Croydon slip arose from the same cause, but, though so much larger, no accident occurred. In the late accident there were but thirty or forty waggon loads of earth, and all was right again in a few hours, while in the Croydon slip 3,000 or 4,000 cubic yards of earth fell; the soil in both instances consisted of the London clay, with pot-holes of sand. It was clear that the accident was not to be set down as one of cutting, similar slips having taken place upon cuttings not more than twelve or fourteen feet deep. He must impress upon the minds of the students that it was not the length or depth of the cutting which regulated the slopes, but the soil and practicability of drainage; unfortunately it was impossible to know exactly how these matters might stand, experience alone could teach them. He had dwelt long upon this subject, but he

wished it to be understood that it was well-judged economy he advocated, not such as would, in the least degree, tend to produce such fatal effects as in the case previously alluded to.

The balancing of the line was equally necessary for railroads as for canals or common roads; it should be the engineer's aim that the quantity of earth from the cuttings should be as near as possible sufficient for the embankments; compared with former times, the mode of transit was so much facilitated, that where some years back it was necessary that the balance line should be limited to the hill to be cut through, and the valley to be filled up, now the line might extend two or three miles. It was essential in balancing that the engineer should be aware of the different degrees of compressibility of the matter; it was known of sand that it would occupy the same cubic contents in the embankment as it did in the hill, and one yard or 100 yards of gravel would be still the same, but in clays it was very different, they occupying less space in the embankment than they did in the hill, in their original position; 100 yards of clay would not make 100 yards of embankment, the average amount of compressibility being not less than 10 per cent., or even, upon occasions, as much as 15 per cent. He had known occasions when 100 yards cut from a hill had only made 85 yards of embankment, but, upon an average, it would require 110 yards of clay to make 100 yards of embankment. Rock cuttings, on the contrary, expanded, because the solid rock could never again be restored to the same degree of density; the difference would vary much, according to the size of the fragments, but where the pieces were large, 100 yards would make 120 yards of embankments.* Chalk, again, would be rather upon the excess, though much depended upon its quality. In rock cuttings you might make them nearly perpendicular, but in chalk much discussion† has arisen as to what was the proper slope, some engineers having even recommended that it should overhang the road, but he contended that it should slope, to carry off the water; he had found a slope of one quarter to one generally sufficient. Rock chalk would stand perpendicular, while several of the softer descriptions would require a slope of one-half to one, or even two to one.

The Professor then proceeded to speak of the correct mode of computing the quantity of earth in a cutting or embankment, and made a section of a hill half a mile long, to be cut down, the true cubic contents of a portion of which was 332,000 cubic yards, computed according to the prismoidal formula; but the ordinary method by which contractors would calculate the contents of the hill, by mean heights, would only show 310,000 cubic yards—that is to say, there would be a difference of 22,000 cubic yards against the contractor, the consequence of which had been, that the person contracting to cut down such a hill, at so much per yard, would lose, from his bad method of calculation, above £1,000. Another method was also in use—calculating by the mean area; which system, instead of 332,000 cubic yards, would show 376,000 cubic yards, being an excess in favour of the contractor of 44,000 cubic yards. Many contractors had realised large fortunes by mean areas, and sustained serious losses by mean heights. Having thus shewn the erroneous methods of calculation in use, he then, at some length, explained the prismoidal formula, accompanying his instructions with many diagrams, without which any attempt at explanation on our part would be useless. The learned Professor concluded his lecture by strongly recommending a close study of mathematics to the junior (all) students, as the greatest assistance to the labours of the civil engineer.

Embellishments of London.—We have heard it stated, and we believe on good grounds, that a great and striking improvement is about to be made in the appearance of Piccadilly, consequent upon the removal of the ranger's house in the Green Park, which will be demolished early in the spring. This tasteful suggestion, we have heard, was made by the Premier, and is to consist of a noble terrace and public walk, from the gate into the Palace-gardens at Hyde Park corner, to the junction of the houses at the lower end of the basin. The form of the ground on this line is particularly favourable to picturesque effect in laying out and planting, and to architectural beauty of design in the esplanade. Fountains and statues, too, are likely to be introduced, to add to the grandeur of the plan. give encouragement to the arts, and combine the whole with the palatial residence of the Sovereign, by carrying it, perhaps, further on hereafter, along the line opposite to Grosvenor-place. The magnificent equestrian statue of Wellington, now casting by Wyatt, will surmount the arch facing Apsley house; and was no reason why it should not be balanced at the other termination by a statue of Sir Robert Peel, together with his name to the work, the idea of which, as we have mentioned, is understood to have emanated from him. At all events it will be a splendid embellishment of this principal street in entering the capital from the west.—*Literary Gazette.*

* These remarks strongly corroborate those of an American engineer, inserted in the Journal of December last.—Ed. C. E. & A. JOURNAL.

† See the evidence on the Brighton Railway before the House of Lords.

IRVING'S TILE MACHINE.

In the last number of the *Journal*, page 8, we gave a plan and description of this machine, which was not properly understood from the want of the annexed perspective view of the apparatus, which we have since had drawn.

THE INDUSTRIAL STATE OF BELGIUM.*

THE Belgians, besides a soil made fertile by their own exertions, possess in their mines of coal and iron the elements of a great manufacturing power; and we have already found them, by their productions of cotton and woollen cloths and hardware, formidable rivals in many foreign markets. Once the tame occupants of the battle-field of Europe, they have now in this age of peace availed themselves of their frontier position, to harass the trade of the surrounding countries; often, it must be acknowledged, by expedients not the most justifiable. The only characteristics which the Belgian tribes possess in common, the only features of a national organization, are of a very unpromising nature; but it takes time to make a nation, and give it the high-souled character of a great community. We do not complain of the Belgians for employing English workmen to beat us out of the market, for that is rather a good accessory of a disposition to enterprise; but we fear that the spirit of piracy, which breaks out in their literary undertakings, is too deeply-rooted, and that its demoralizing influence will long affect them. We find the Belgian journals ever holding forth to public attention some promised wonder of native growth; but we do not find, on after-inquiry, that these visions and speculations are ever brought to any tangible form. The spirit of imitation is a good one; but that of piracy is so demoralizing in its influence on the mind, that we cannot augur well of future success to Belgian enterprise. It will take many years before the Gascons of the north can be sobered down to the business-like pursuits of a steady people; and until that takes place, England has little to fear from their rivalry. These are remarks which are not unnaturally suggested to us, when we read the præm of a new Belgian periodical, devoted to the industrial arts. "Belgium," says the author, "occupies, without fear of contradiction, a first-rate position among manufacturing nations, as the brilliant exhibition of its productions demonstrates to every eye." This is an introduction so truly Belgian, that we shall be prepared for any future escapade of our new contemporary.

Until the present time, it appears that, with two exceptions of works produced by the editor of the one now founded, no periodical devoted to the mechanical sciences has yet been attempted in Belgium. We are rather surprised at this, but we hope that the effort now made may be successful. Belgium, it is known, has at Brussels a very fine museum of the industrial arts, which is thrown open to the public, and is a favourite Sunday walk of the working classes. The Director of this museum is M. Jobard, a gentleman to whom Belgium is much indebted for his exertions. The state of school instruction is very good; but the point in which the Belgians are mainly deficient is in a workmanlike character, which is not to be created in a moment. The number of patents issued in Belgium is pretty large, but they form no

criterion, either of the progress of the arts, or of the ingenuity of the Belgian people. We find that the numbers are:—

1830	5	1836	76
1831	15	1837	134
1832	30	1838	280
1833	42	1839	269
1834	48	1840	326
1835	62		

The small number in early years is to be accounted for by the effect of the revolution, and the embarrassments of the country.

THE "SLIDING SCALE."

SIR—Being fond of the combination of utility and simplicity, I send you an idea of a "*Sliding Scale*," not for debate in the House of Commons, I assure you; but to be submitted, through *your* journal, to the judgment of the honourable professions of the civil engineer and Architect, for their universal adoption. The sliding scale I propose is to be drawn on a separate strip of paper, and substituted in lieu of or in addition to the present one usually put on plans, maps, sections, &c. It may be in length proportioned to the size of the plan, and about half an inch in width, of the same paper, and kept always with it, by being slid through two or three cuts made with a penknife at right angles to the roll of the paper. There it lies, and is available at a moment's notice, for examining the plans as to details, additions, alterations, and so forth. About five minutes extra care in drawing this scale makes it an invaluable attachment to any plan. The experience of almost all persons conversant with these matters must suggest cases of occasional great inconvenience arising from not having a pair of compasses, plotting-scale, or even rule, aye, or pencil at hand, at the moment when most wanted, say in a field, on a scaffold, when exhibiting designs to directors, noblemen, gentlemen, &c., by your having put on hastily your No. 1 coat, to be punctual to appointment, leaving all your conveniences in the pocket of your working one, snug in your study. In some instances very unusual sizes for plans may have to be adopted; and here, too, the sliding scale becomes useful. Trusting to the valuable assistance of your vote, in my endeavour to pass the above suggestion, on its announcement in your February number,

Believe me, Sir,
Your obedient servant,
W. BEWLEY.

Dublin, Jan. 19, 1842.

P.S. By way of addendum, in reference to the *last* letter on his vernier reading-staff (staves, I doubt,) of Mr. T. Stevenson, and his few parting words,—I am sorry, for his sake, my estimate of his *improving* qualifications was so just.

* Bulletin du Musée de l'Industrie. Brussels.

REPORT ON THE GAS FURNACES USED IN THE IRON WORKS OF WASSERALFINGEN, BY M. H. SCHOENBERG.

(Translated for the C. E. and A. Journal, from the *Bulletin du Musée de l'Industrie.*)

ONE of the most important modern improvements in the manufacture of iron we owe to M. Fabre Dufaure, Mining Counsellor, Director of the iron works at Wasseralfingen in Wurtemberg, who has succeeded in collecting from the chimney the gases which are formed in blast furnaces, which constitute the flame which escapes, and to use them as fuel in the refining, puddling, and belling furnaces.

The use of the furnace flame for several purposes, as warming the air used for the blast, roasting lime and ore, making coke, and heating steam engine boilers, has been known these seven or eight years. It has not, however, been hitherto practicable to produce a higher temperature than red heat, which was a limit to its application; while by M. F. Dufaure's process any degree of heat required may be obtained. The principal distinction of this method is in the mode by which the gas is burned, by the introduction of atmospheric air supplied by bellows, and in the ingenious construction of the furnaces and fire-places.

At Wasseralfingen there are now three furnaces in use worked by gas, but the refining furnace is supplied from the southern blast furnace alone, which is done by simply introducing a tube to a certain depth in the fire-place of the blast furnace. It appears that about a sixth or a fifth of the gas evolved is collected by this method; and, notwithstanding this subtraction, no diminution is observed in the power of the flame which escapes. In the refining furnace there are thus produced 175 metrical quintals of fine metal, partly with a radiated crystallization, and partly with a ball-like structure, but all of a silver white. The gas refining is so complete, that the iron is produced highly decarburized, and freed from all impurities; among others, from phosphorus and sulphur. The waste, which in common English refining is never less than from 9 to 10 per cent., is not more here, when the furnace is in good order, than 1 to 2 per cent.; and by this process a greater quantity of fine metal is obtained than if pig iron had been used. It is to be further observed, that the pig iron passed through the furnace here consists only of castings, which, as is well known, have often a good deal of sand mixed with them.

The operation is so well arranged, and proceeds with such uniformity, that it rarely meets with those casualties common in the usual process of refining, while the cost of manual labour is also less.

The results of puddling by gas are not less satisfactory. The puddling furnace at Wasseralfingen is supplied with gas from the northern blast furnace, into the fire-place of which are plunged two suction pipes, by which enough gas is collected, to work a puddling furnace and a refining furnace; but the power of the water-wheel which works the blast apparatus not being great enough, these works can only be supplied alternately. The temperature of the puddling furnace is, from the nature of the process, higher than that of one fed with wood, coal, or turf; the flame also is clearer, and transparent, so that the workmen can easily watch the operation, and carry it on regularly. In each of these operations the furnace is charged with 1½ or 2 metrical quintals of fine metal, previously heated to a red heat by another furnace; and at the end of an hour and three-quarters, or two hours, the effect is produced. The waste of fine metal in this process is very small, the mean being only from 1 to 2 per cent. The quality of the iron is excellent. A feature peculiar to gas-puddling is that the formation of slag and its reduction goes on simultaneously, so it is never thrown away. The produce of the puddling furnace is 125 metrical quintals per week.

The operation of refining in the gas furnace has, like the preceding, considerable advantages; but the results have not yet been so important as in the preceding cases, and the quantity of waste is still considerable. The draught of the furnace is good, and the temperature sufficiently raised; so that, unless an accident occur, the produce is 150 metrical quintals per week.

From what has been already said, it will be seen that the results of the gas furnaces at Wasseralfingen are most satisfactory. Even with castings and rubbish, bar iron of excellent quality is produced, with a waste of not more than from 12 to 15 per cent., and without any consumption of costly fuel, or rather, by making use of a combustible matter, which hitherto has not been turned to account.

Belgium is the only country in which M. Fabre Dufaure's process has not been introduced, while in other places it has been extensively used. In England, at Messrs. Hill's works, at Merthyr Tydvil; in Germany, at the iron works of the King of Bavaria, Grand Duke of Baden, Princes of Furstenburg and Sigmaringen, Duke of Anhalt, the

Saxon Iron Company, Count Einsiedel in Prussia, &c.; in France, at Lucelle; in Hungary, at the works of Count Andreasky and M. Inglo; in Russia, at those of the Prince de Bukna and Count Malzon; in Sweden, at Mr. Ekmann's; and in Italy, at the works of Dorgo, on the Lago di Como.

At one of the last meetings of the French Institute, M. Dumas read a letter from M. Grouvelle, giving some further particulars not contained in M. Schoenberg's report, as to the process used by M. de Fabre Dufaure in the iron works of Wasseralfingen. The practice is to carry into the refining furnace the pig iron delivered from the high furnaces, and not cold iron, as is usually done. The object is to save the caloric employed in the fusion. The puddling furnace produces 10,000 kilos, or about 9½ tons of iron per week. At this time a third blast furnace is being constructed, and steam engines are being put up, to work the gas plan on a large scale. M. Fabre Dufaure's first experiments began in 1837, and took place on refining cast iron; and the processes used by him at Wasseralfingen were kept secret until the present time, by desire of the King of Wurtemberg, who was unwilling that they should be known immediately in other countries.

After making this communication, M. Dumas reminded the academy that he had received about two months ago specimens of iron obtained in France by gas puddling in blast furnaces, by means of the process adopted at the iron works of Treveray, by the proprietors, Messrs. D'Andelarre and Lisa, and by the engineers, Messrs. Thomas and Laurens. He added, that the puddling furnace set up at Treveray has worked very well, and has already sent produce into market. In this furnace is refined iron, which is produced in the same way as by the common puddling furnace used in Champagne. The gas of a single blast furnace producing 5 cwt. of iron per day is enough to feed it; a result which proves that all the cast iron produced may be converted into bar without farther fuel, while such a result cannot be deduced from the work at Wasseralfingen, where the quantity of iron produced even at present is much smaller than the quantity of cast iron afforded by the two blast furnaces at those works. M. Dumas states the advantage of the Treveray gas plan to be an improvement in the quality of the iron, which has all the properties of charcoal iron, a considerable diminution of waste, and a great saving of fuel. It is to be further observed, that no effect is produced on the blast of the furnaces from the shafts in which the gas is collected. M. Dumas remarked to the academy a passage in M. D'Andelarre's letter, that the idea of using combustible gases for the same purposes as other fuel had been long since suggested by M. Thenard, in his public lectures; and the importance of these processes, which promise much, lies principally in the apparatus, which has enabled them to be successfully used.

THE ROYAL EXCHANGE.

We had hoped that the silly, nonsensical fias of "first-stone-laying" was nearly gone out of fashion. The ceremony of the kind which has just taken place at Cornhill must have been a somewhat expensive one; and so far perhaps may augur well, as an indication that no cost will be grudged in decorating and finishing up the new Royal Exchange, not forgetting sculpture to the pediment of the portico. Still, the money which has been so idly squandered away, might have been laid out with some little degree of reason, had it been applied to the erection of a temporary model, formed of timber and canvass, of the portico itself, executed on the intended scale, as has been sometimes done in France. A full-sized model of that façade of the Exchange—which might have been allowed to remain until that part of the structure shall be actually commenced—would have enabled us to judge what effect the portico will have upon the Bank, and other buildings in its immediate vicinity. It would have been better still, had the money expended upon a mere brief and unmeaning ceremony, been appropriated as the nucleus of a fund towards a new façade to Guildhall, since nothing can be more detestable than the present one.

Engineers' Convention.—It is announced that the Chevalier de Weebeking, the engineer of the railways between Munich and Augsburg, Fûrth and Nuremburgh, is about to issue a circular, inviting all the celebrated railway engineers to assemble at Munich, in the course of the present year, for the purpose of mutually communicating information on the construction and working of railways. We very much doubt the utility of such a meeting.

REVIEWS.

Domestic Architecture: containing Principles of Designing Public Buildings, Private Dwelling-houses, &c. &c. By RICHARD BROWN, Professor of Architecture. 4to. Part 1—13.

THERE are occasions on which to show lenity would argue either stupidity or dishonesty, rather than mercy; and most assuredly the present is one of them, for scarcely ever have we met with a more egregious specimen of arrant book-making, of quackery and charlatanism, than this publication. Of quackery and impudence the very title itself bears evidence, the author there assuming to himself the style of "Professor of Architecture!" Undoubtedly any man may call himself "Professor" of anything, if it so pleases him; yet, as custom does not warrant the use of the term as signifying no more than one who follows any particular trade or calling, the self-assumption of it is so far from conferring any respectability, that it is rather a sign of vulgar-mindedness, and low paltry artifice. Absurd at the very best, this kind of self-bestowed professorship becomes doubly or trebly so in the case of Mr. Richard Brown, since he might with equal propriety have signed himself Professor of Poetry. Whether he has any qualifications for setting up in the latter character, we know not; but we do know that he possesses none whatever for that of a professor of the other art, it being very plain that, instead of being at all capable of instructing others in architecture, he is most profoundly ignorant of it, even of its first rudiments, and the commonest principles of taste, and that he needs to go to school, though we question whether it would be to any purpose.

The work is altogether a very flagrant instance of "Catch-penny."—Why then, it will be said, bestow any notice on it? why drag it from its obscurity? why not pass it by with silent contempt?—Because it is, in our opinion, a very fit subject for castigation. The treating offenders of the kind merely with contempt, is nothing else than granting them impunity. What care they for contempt, who know themselves to be contemptible pretenders, and who are utterly indifferent to public opinion, that is, to the opinion of the intelligent, provided they can but impose upon the ignorant and credulous, and obtain their favour and patronage? Exposure they may dread, contempt they only mock at. We do not say that even exposure does much good, as far as correcting the offenders themselves goes; still it is attended with salutary effect, opening the eyes of the public, by putting them on their guard against productions of the kind, and by making others shy of risking similar castigation. Were publications of the kind merely worthless, they might be allowed to pass without very strict inquiry; but they are, on the contrary, positively mischievous, since they not only do not promote good taste, but diffuse the very worst, amongst workmen and mechanics. It is to trash of this kind, published under the name of collections of "Designs," that we may ascribe those abortions and monstrosities in brick and mortar, which spring up in various parts of the country. Instead of promoting the advancement of the art, they positively retard it; and instead of being at all creditable to any one concerned in them, they cast a sort of slur upon the whole profession, and tend to bring the very study of architecture into contempt.

It certainly is most mortifying to reflect upon the humiliating light in which foreigners must look upon the present state of the art in this country, if they judge of it,—as they are most likely to do,—from such publications as the present one and some others; more especially, if to their appearance be added the *non-appearance* of architectural works of a higher order, of which there certainly has been a great dearth of late, far more so than used to be the case when the profession was by no means so numerous as at the present day. Whatever may be the cause of this—whether it be partly owing to a very increased demand in this country for foreign architectural works, in preference to those of our own production—we pretend not to judge. Such is the fact; and it is one that has been stated by other writers, not without some degree of bitterness. Let the remote cause be what it may, there can be little doubt that the immediate one is the want of encouragement among us for works of the same class as are continually issuing from the publishing houses of France and Germany. Hardly is the profession any more lucrative on the continent than in this country, else that circumstance might be taken as a sufficient explanation of the matter; yet, such not being the case, we must leave our readers to account for it in the best way they can,—satisfactorily, if they can; although it is anything but satisfactory in itself.

At all events, it is deplorable enough that, while very inadequate encouragement is given to works which would be really creditable both to the art and to the profession, there should be any at all for the

vamped-up, catch-penny productions, of which the one before us is so egregious a specimen. As for the literary portion, it consists either of mere scissors-and-paste work, or of the most irrelevant, far-fetched rigmarole, that can well be imagined, and a great deal of what, if not actually absurd in itself, becomes absurd, when *lugged in* for the nonce, as we here find it, without having any sort of connexion with the subject or the occasion. What, in the name of common sense, has the mention of antediluvian architecture, or meagre, schoolboy sketches of the history of Egyptian and other still less known early styles of antiquity, to do with modern "Domestic Architecture,"—more especially in a volume of designs for ordinary villas, or rather, of villanous designs of most extraordinary ugliness? Very far more discreet would it have been, to have omitted the mention of styles altogether, since the less people understand about them, the more likely they will be to tolerate those samples of them which the Professor here exhibits, and which most convincingly prove that he has not the very slightest knowledge of any one style whatever, his designs being actual burlesques upon the different styles they purport to exemplify. Evident it is also that he cannot yet copy the Grecian orders, for the three figures pretending to represent them are only monstrous caricatures. In fact, the drawing of all the plates is most atrociously bad, so bad as to be the only consolatory circumstance of all. Had the plates themselves been tolerably well drawn and engraved,—had they been, in young-lady phrase, "exceedingly pretty,"—we should have been almost in despair; but, as good luck would have it, they are so wretched in every respect, as to display the designs in unmitigated ugliness; consequently, the mischievousness of the work is so far neutralized. The designs now show themselves at the first glance to be utter trash; whereas, had they been flattered by the engraver,—had they been managed with a little taste and adroitness on his part,—the ignorance, the blunders, and the barbarous ideas they display, might perhaps have passed undetected by the class of persons among whom the Professor, or his publisher, looks for customers. As it is, no one, we feel morally assured, that is, no one who is not a candidate for Bedlam or some county asylum, will be ambitious of building for himself in the Brownian Florentine, Tudor, Flemish, Stuart, or any other style whatever, according to the learned Professor's notions of it. But, hold! the suspicion has just come across us, that, after all, the Professor is neither more nor less than a wicked, prankish wag, who, in order to discover how far gullibility will go, has here maliciously put forth a series of hoaxing, farcical caricatures, as examples of the respective styles, and perhaps as a covert satire on the affectation of imitating all sorts of outlandish styles, and that in the most barbarous manner. Certainly such must be his intention in regard to the specimen he has given us of the Grecian style, which partakes far less of Greece than it does of my grandmother; therefore, as the character of Grecian architecture is now tolerably well understood, he would hardly have ventured upon such an example, except as an obvious burlesque. In his design for an "Anglo-Grecian Museum," he makes a scurvy bit at Soane, caricaturing his architectural eccentricities most unmercifully; and, among other freaks, placing Ionic columns with the baluster side of their capitals outwards! The section of the building, in which this Anglo-Grecian peculiarity manifests itself, is further remarkable for the *scientific* construction of the roof, and for showing Doric columns with chamber-pot-shaped capitals supporting arches, another Anglo-Grecian peculiarity!—the said columns being very little higher than the hand-rail of the staircase. Lest the drift of the satire should by any possibility be misunderstood, this plate is entitled "Soanean Museum, section and component parts," the last being little better than the scrawls an idle boy would make upon his slate.

If he chooses to avail himself of it, we give the ingenious Professor the full benefit of our suspicion; but if he rejects it, we must set him down as one of the greatest ignoramuses that ever ventured before the public. It is really astonishing that a person who shows himself so thoroughly incompetent in every respect, so utterly destitute of every qualification, should have the effrontery to offer to the public a parcel of disgracefully miserable drawings,—so execrably vile, that it is incomprehensible how any respectable, or how any publisher at all, could be induced to touch them. It is possible that the latter party may have been imposed upon, and, owing to his own ignorance of the subject, has been led to that which, as a respectable and fair-dealing tradesman, he otherwise would have rejected with scorn, and not lent himself in any way to such a piece of impudent quackery.

However devoid of merit they may have been in themselves, we have generally been able hitherto to pick up a serviceable idea or hint, from productions of the kind. Not so, however, from Professor Brown's: his designs are as dull as they are hideous; they offer nothing whatever that can, by any possibility, be shaped to any purpose. His plans are about as absurd as his elevations; certainly most

clumsy, and without any sort of study or contrivance; while, as to the few sections he has given, they are perfectly ridiculous; nor do they always correspond with the ground plans. If there be still a degree of worseness, a "lower depth within the lowest deep" of vileness, it is manifested in the details, or "component parts" of the accumulated deformity here presented to us.

That we are severe, we do not deny; but we cannot possibly be too severe, on the present occasion, for we hold this publication to be thoroughly disgraceful to all concerned in it, and nothing less than a positive insult to the architectural profession, and a libel upon the architectural taste of the country, in the middle of the nineteenth century. Far better architectural designs than those of this Professor may any day be seen at almost any confectioner's shop-window. They are in fact so supremely wretched, that it is utterly impossible to convey any idea of their preposterousness, by words alone; and were it not that it actually is published, we should say that no one in his senses would publish such execrable trash. It is matter of doubt with us after all, whether the Professor be really in his senses, for his drawings manifest as much insanity as did those of Messrs. Baddock and Buckland for the Houses of Parliament, which some of our readers will perhaps recollect, and which certainly struck with amazement all who beheld them. How far it is a proof of sanity, or the contrary, on the part of the Professor, that he intends to give his own portrait in the concluding number of his work, we leave our readers to decide. Probably he may be, or may fancy himself to be, a perfect Adonis; but unless his own face be very much better than his façades, he must be a perfect scarecrow.

London Bridge, Drawn by B. Albano, M. Inst. C. E. and M. R. I. N., and engraved by Lowry. London: Weale, 1842.

WE have received a magnificent engraving of London Bridge, from the drawing of Mr. Albano, executed by Lowry in his best style, being one of the finest delineations of an engineering work which has yet appeared. This print, from a plate 3 ft. 6 in. by 2 ft., possesses an accuracy and fidelity which are the best qualities of such a work; while as a production of art it is truly splendid. As the engraving depends for its importance on the bridge itself, we think it better to give some account, from Mr. Albano's notes, of the dimensions of this triumphant monument of Sir John Rennie's skill.

The drawing was presented by Mr. Albano to the Institution of Civil Engineers; it was made with great care and accuracy, from dimensions taken by him during the progress of the works.

Centre arch 151 ft. 9 in. chord, 37 ft. 10 in. rise.
 Piers on the side of centre arch each 24 ft. in width at springing.
 Arches on either side of centre 140 ft. chord, 37 ft. rise.
 Piers of land arches each 22 feet in width at springing.
 Land arches on each side 130 feet chord, 33 ft. 10 in. rise.
 Total length of bridge from face to face of abutments 783 ft. 9 in.
 Width of water way at spring of arches 691 ft. 9 in.
 High water Trinity datum 8 ft. 4 in. above spring.
 Low water Trinity datum 10 ft. 1 in. below spring.
 Length of bridge from end to end of abutments 1005 feet.
 Width of bridge from cut to cut 56 feet.
 Width of carriage road 35 ft., of each foot path 9 ft.
 Greatest depth of foundations 23 ft. 7 in. below low water datum.
 Total number of piles, forming the coffer-dam 7708.
 Total number of piles, 20 ft. long, under piers and abutments. 2092.
 Quantity of granite and stone used in constructing the bridge and abutments, 120,000 tons.
 First pile driven 15th March, 1824. First stone laid 15th June, 1825.
 First arch keyed 4th August, 1827. Last arch 19 Nov. 1828.
 Bridge completed and opened 1st August, 1831.
 Cost of the bridge £542,150.
 Cost of the bridge and approaches, including alteration and removal of old bridge, £1,401,234.

Examples of Inlaid Gothic Tiles. London: Nichols and Son, 1842.

THIS work comes very acceptably at a period when so much attention is directed to the details of architectural ornament. Encaustic tiles are to be met with extensively in our cathedrals and ancient churches; although it is only of late years that they have been re-introduced. Mr. Harvey Eginton was, we believe, the first to use them in 1837, in the repair of Stratford-on-Avon Church, and they have since been used at Wilmcote Chapel, near Stratford; St. Michael's, Worcester; St. James's, Malvern; the Temple and St. Mary's, Stafford.

The little volume before us contains engravings of twenty-four specimens of tiles, the size of the originals in Winchester Cathedral, Romsey Abbey Church, St. Cross, Winchester, Warblingam Church, and Worcester Cathedral. These illustrations are nearly all from Hampshire, so that as the mode of engraving is cheap, we hope to see similar works for other districts.

The editor of this volume has done considerable service by leading the way in the illustrations of such an interesting subject.

A Familiar Explanation of the Nature and Importance of Assurances upon Lives. By LEWIS POCOCK, F.S.A. London: Smith and Elder, 1842.

To professional men, more than to any other class of persons, the importance of life assurances is strikingly great. Too often, although in the receipt of large sums of money annually, they are led, by the necessity of maintaining an appearance in society, to expend their whole income, so that, in the event of death, their families would be left entirely unprovided for: whereas, by appropriating a portion of their revenue to assure the payment of a certain sum of money to their relatives, after their death, all solicitude is removed, and, in the words of the intelligent author of the book before us, "a safe termination to an uncertain event is secured."

Strange to say, the principle of life assurances is but little understood, their advantages but slightly appreciated. It is the object of Mr. Pocock's book to set the whole matter in a clear and familiar point of view, to explain the different systems of assurance now in use, and the routine required for effecting a policy. It likewise contains the principles, terms, and tables, of seventy London assurance offices, and forms altogether a perfect *vade mecum* for those wishing to understand, or desirous to avail themselves of the many advantages arising out of this very important species of assurance. We hope, as much for the sake of the public as of the author of this useful little book, that it will have a large circulation.

We have from Mr. Ferdinand Pelzer, *A Practical Guide to Pianoforte Playing*, of which we ourselves do not profess to be judges, notwithstanding the injunction of Vitruvius as to the intimate union of architecture and music. We have referred Mr. Pelzer's work to the female department, and are told that it is calculated to be useful to the young student.

ON THE DECORATED BUILDINGS OF LONDON.

WHILE so much attention is being devoted to the introduction of the other arts into public buildings, it may be of advantage to the advocates of decoration to have a list, although an imperfect one, of those buildings in the Metropolis in which it has been already applied. Theatres and places of amusement it will be unnecessary to enumerate, so that we shall turn our attention to other edifices.

St. James's Palace has painted ceilings in most of the state rooms and staircases.

The ceiling of Whitehall Chapel, painted by Rubens, represents the apotheosis of James I.

The grand stair-case and ceilings of the principal rooms of Kensington Palace were painted by Kent.

The Painted Hall of Greenwich Hospital was executed by Sir James Thornhill, and the ceiling of the Upper Hall is also painted, representing Queen Anne and Prince George of Denmark, surrounded by various allegorical figures. The Chapel has been ornamented by the pencils of West and others.

The British Museum, now about to be pulled down, is too well known to require any description. The artists employed have been Charles de la Fosse, Jacques Rousseau, and Rigaud.

The dome of St. Paul's was ornamented by Sir James Thornhill with paintings illustrative of the life of St. Paul.

The Roman Catholic Cathedral of St. Mary, in Moorfields, is painted throughout.

The Duke of Beaufort's House was recently painted by Mr. Latilla and Mr. Owen Jones; descriptions of it will be found in the Journal.

The Hall of the Society of Arts is indebted to the pencil of Barry.

The Library of the Royal Academy has a painted ceiling by Angelica Kauffman.

The ceiling of the Library in the Soane Museum was executed by Howard the Academician.

The Reform Club is one of the most brilliant modern specimens, the whole of the decorations of which have been executed from the directions of the architect Barry.

The Hall of the Drapers' Company, in Throgmorton Street, is well arranged.

The stair-case of St. Bartholomew's Hospital, painted by Hogarth, at his own expense, represents the Good Samaritan and the Pool of Bethesda.

Many private houses have painted ceilings. That in Buckingham Street where Peter the Great resided, the House of the Westminster Discon Company, the Linnean Society's House in Soho Square, &c.

COMPETITION DESIGNS.

MR. EDITOR.—By inserting the following account of a competition job, in your widely circulating journal, you will enable me to fulfil my promise to the perpetrators of it, and contribute something to the general tide of indignation against the system as now practised.

In June last the Commissioners appointed under an Improvement Act, advertised for designs for a Pump Room at Low Harrowgate, and stated, amongst other particulars, that no premium would be given, but that the architect producing the most approved design would be employed to carry it into execution. This bait drew designs from about twelve architects, all, like myself doubtless, expecting they would have fair play in return for their expenditure of time and talent. The designs were sent in, and the Commissioners met on the 16th of August following; the meeting was then adjourned to the 20th; and again to the 6th of September for final decision. Being at Harrowgate on the eve of the last named day, I was astonished to learn from several of the Commissioners, that Mr. Strutt, one of the competitors, and a native and resident at Harrowgate, had prepared another design, introducing a prominent feature of my own design (a dome) which had been privately handed round amongst the Commissioners, preparatory to its being introduced at the meeting for the final decision. Though I strongly remonstrated against this most dishonourable proceeding, the drawing was actually brought into the Commissioners' Room by one of the body, but the Reverend Chairman, together with some others, would not sanction it to be produced. On dividing, my design was rejected, and Mr. Strutt's chosen by a majority of five; after which I received the following note from the chairman.

"High Harrowgate, September 6, 1841.

"SIR—Being of opinion that the plan for the Harrowgate Pump Room has been decided not upon *merit*, but by favour, I beg to inform you that I have withdrawn my name from the list of Commissioners in consequence. It will not be unsatisfactory for you to know that I gave my vote in favour of your design, as in my judgment the best offered to the acceptance of the Commissioners, at the estimated cost prescribed in the instructions given by them.

"I remain, Sir, your obedient servant,

"To Mr. Mallinson, Architect,
Brighouse."

THOS. KENNION."

And which was afterwards endorsed by two others of the Commissioners—

"Mr. Charlesworth expresses his perfect concurrence with the above remarks of Mr. Kennion."

"I also beg to give my testimony to the foregoing, and have withdrawn my name from the list of Commissioners in consequence.

J. G. PALEY."

Captain Thackwray (who was prevented from indisposition from attending the meeting) and Mr. Dearlove subsequently withdrew their names for the same reasons. I understand the Chairman also addressed notes to all the excluded competitors, stating his opinion of the transaction.

The Rump (probably alarmed at this serious defalcation from its numbers and respectability) then attempted a compromise, and proposed that I should be joint architect with Mr. Strutt. To this I stated my readiness to accede, provided they would revoke their precious decision, and give the award to me. This being objected to, after freely expressing my opinion of their conduct, I took my leave, not without the hopes expressed, after a long interval (for reasons therein stated) in the following:—

"To the Commissioners appointed under the Harrowgate Improvement Act.

"GENTLEMEN—I have hitherto been silent on the subject of the architectural competition for the Pump Room, Harrowgate, hoping that due reflection, and the secession of five of the most influential members of your commission, would have led you to reverse the partial and most unjust decision, by which a majority of your body rejected my design.

"The letting of the works and laying of the stone have been managed with a secrecy so unusual in such cases, that I have seen no notice of either in any public print. Your advertisement for a loan, a few weeks ago, led me to make inquiries, which have informed me of the commencement of the building, and the consequent futility of my expectations.

"Presuming you to be not indifferent to the good opinion of your fellow-townsmen, and wishful to pass for men of character and honesty, you are bound to disprove the charge made against you in the note addressed to me by the Chairman and other retiring Commissioners, a copy of which I herewith enclose. It is due to myself and the other competitors, as well as to the profession generally, that the particulars of this unprecedented transaction should be made as public as possible. I, therefore, ask you for copies of the design first sent in by Mr. Strutt, which you selected as the best; also of the one now being carried into execution (which I presume to be the amended one sought to be substituted in place of the first one, *before* the competition was decided!), in order that I may publish them together with my own design, and thus afford the public an opportunity of judging between us. I need not add that your refusal to comply with this request will be a tacit admission of the correctness of the charge.

"I remain, Gentlemen, your very humble servant,

"Brighouse, near Halifax,
December, 27th, 1841."

"JAMES MALLINSON."

This produced the following reply—

"Committee Room, Harrowgate, Dec. 27, 1841.

"SIR—I am requested by the Commissioners, in reply to your letter applying for copies of Mr. Strutt's plans for the Pump Room at Low Harrowgate to inform you that they cannot comply with your request; and, that they do not consider you have any right to ask for them.

"I am, Sir, yours obediently,

"S. POWELL, Jun."

Being thus for the present deprived of the benefit of the comparison, I am compelled in some degree to be both plaintiff and judge. But having seen all the designs, I can conscientiously affirm, that, with perhaps *one* exception, the approved design was the most unsuitable for the situation. Several designs of merit were cast aside, almost without examination, for the whole and sole reason, that their estimated cost exceeded the stipulated sum of £1,500, and yet this approved design was estimated to cost only £1,900!!! What the amended design may be I know not, but I intend to send you a sketch of it when completed, also of the original one, of which I have a sketch from recollection, made immediately after seeing it, together with my own, that you may judge of the correctness of my assertions; meantime,

I remain, Mr. Editor, your very obedient servant,

JAMES MALLINSON.

P.S. One of your correspondents suggests, that in such cases the names and occupations of the parties should be given. I consider his suggestion a good one, and give them, first apologising to my supporters for placing their names in a company they have so long repudiated.

FOR.

Reverend Thos. Kennion, Incumbent of High Harrowgate Church.

John Green Paley, Esq., Magistrate.

Charles Charlesworth, Esq., Gentleman.

Mr. John Dearlove, Innkeeper.

Mr. Nicholas Carter, Wine Merchant.

Mr. Thomas Gordon, Proprietor of the Cheltenham Pump Room.

AGAINST.

Mr. Jonathan Benn, Retired Innkeeper.

Mr. Thomas Hall, Innkeeper.

Mr. George Hobkinson, Milkman and Boarding Housekeeper.

Mr. George Knowles, Plumber.

Mr. George Morely, Baker and Grocer.

Mr. George Harper, Innkeeper.

Mr. Richard Stanning, Innkeeper.

Mr. Joseph Waite, Druggist.

Mr. Richard Whincup, Porter Dealer.

Mr. Christopher Wright, Coach Builder.

Mr. J. H. Walker, Wine Merchant.

RAILWAY WHEELS.

MR. PHIPPS, of Deptford Green, Engineer, has obtained a patent for improvements in the construction of railway wheels, the object of which is to supersede the process of "shrinking on," which he proposes to do in the following manner:—

A bar of wrought iron is prepared, by rolling in the usual manner, with an outer flange on one edge, and an inner flange in the centre of the bar; this bar is bent into a circular form, and then welded. Sixteen wrought iron spokes are prepared, with an extended end or palm, which may be drawn out by hammering, or welded on; the inner end of each spoke is jagged or perforated, in order that the cast metal may embrace and hold it fast. Eight of these spokes are then laid in a mould, and one portion of the boss or nave of iron cast upon their inner ends; the other eight spokes have the corresponding portion of the boss or nave cast upon them. The two parts of the nave are then brought together, and secured by screw bolts, and the enlarged ends or palms of the spokes strongly secured to the alternate sides of the inner flange by screw bolts, or by rivetting. Another method consists in placing all the spokes in their respective positions around the wheel, and casting the boss or nave in one piece, the palms of the spokes being afterwards rivetted to the inner flange.

ANOTHER patent has been granted to William Losh, Esq., of Little Benton, Northumberland, for improvements of railway wheels, by the application of wood, felt, rope, or other such like flexible or yielding material, between the inner tire and the ring or felloe, or bearings produced by the prolongations of the bars of iron employed to make the wrought iron spokes, with or without the intervention of a ring of malleable iron between such bearings and such flexible or yielding material; by which means wrought iron railway wheels will be less liable to be prejudicially acted on by the vibration to which such wheels are liable when in use, than if they were composed of iron alone. The wheels to which these improvements are applicable, are those included in the patentee's former patent, of August, 1830.

SUPPLY OF PARIS WITH WATER.

An Englishman of the name of Miles has addressed a memorial to the French authorities, on the subject of a proposed supply of water to Paris. Some of the statistical facts put forward may interest our readers. The city of Paris, he observes, possesses very peculiar advantages for such an undertaking. In London, the quantity of water consumed daily is 168,826 cubic metres (French) for 191,066 houses. In Paris there are about 40,000 houses, which is little more than one-fifth of those in London. The expense of pumping by steam-engines this quantity of water from the level of the Thames at London, to an elevation equal to the Canal de l'Oureq, above the Seine, would cost £69,000 per year, the whole of which would be saved by a supply from the Canal de l'Oureq. The houses in London may be calculated at six persons each, making a population, in 191,066 houses, of 1,146,396 inhabitants. The 40,000 houses in Paris contain 909,126 inhabitants, equal to 22 or 23 to each house, or of four families of six persons each. The length of the pipes required for Paris will not exceed a fourth part that of London, and their dimensions will be less, on account of the descent of the water affording a greater velocity. The exact length of pipes required cannot be stated without a plan and section of all the streets—it is probable that the length required would measure about 170 English miles. If this quantity of iron pipes were delivered at £20 sterling per ton, it would amount to the sum of £480,000
The expense of laying, with the apparatus of cocks, &c., for service, may be stated at 120,000

Making a total of £600,000
Supposing 10 per cent. interest, the sum to be paid annually would be £60,000. At present, it is allowed that Paris pays annually for the purchase of water, not exceeding 50 litres per day for each house, £160,000; so that, upon the present rental, a saving would take place of £100,000 per year, and the inhabitants would receive the most abundant supply of water. M. Girard estimates the quantity of water supplied by the Canal de l'Oureq at 260,820 cubic metres per day. Supposing this calculation to be exact, it will be necessary, first, to deduct all the water necessary for the supply of the present public fountains and markets; and secondly, what is consumed by the locks on the Canals St. Martin and St. Denis, which may be calculated at 1,054 cubic metres for the passage of a barge, or of 105,400 cubic metres for the passage of 50 barges on the two canals. The quantity of water consumed daily in each house in London, in 1810, before the establishment of the new water companies, did not exceed 50 gallons, but since that period the consumption has reached 200 gallons (?) per house per day. This includes manufactures, baths, &c. If a similar increase in the consumption should take place in Paris, the quantity required would be 140,000 cubic metres per day, for the use of the 909,126 inhabitants. London pays annually for water the sum of £284,188, averaging about 32s. (58) per house for six persons; consequently, if Paris were called upon to pay £60,000 per year, it would average about eight shillings for every family of six persons for an equal supply. When plans and sections of the streets shall be made, the engineer-in-chief will be able to construct a system of perfect drainage, parallel to the water-pipes, and of the same inclination.—*Athenæum*.

THE PALMPEDE.

WE have a long account in the *Morning Post* of a newly-invented locomotive power. (the invention of the Marquis de Jouffroy,) said to be applicable to steamers, from which we select the following extracts, describing this wonderful invention; but to our dull comprehension it appears to be a "mountain in labour":—

"The scientific world will readily appreciate the justness of the principles, according to which the Marquis de Jouffroy constructed his machinery, and applied it with complete success, as we can assert, to a schooner of about 120 tons (French) burden, rigged as usual, like a sailing vessel. Her measurement is as follows:—

"Twenty metres 15 (62 feet French) from stem to stern, and 5 metres 20 (16 feet French) beam; drawing when laden two metres forward, and two metres 37 abaft; the area of the parallelogram of the portion immersed amid-ships, 11 metres square, although, on account of the build of the ship's bottom, this area is really but seven metres square. She carries a steam-engine, mean pressure, of from 20 to 40 horse-power, *ad libitum*.

"Abaft the vessel, on deck, is a platform four metres long, moving horizontally on a vertical axis fixed in the stern-post, one half of the said platform being without the vessel, and the other half within: the latter sustains the two oscillating cylinders of the steam-engine, the piston-stems of which communicate the movement, in a direct manner, to an iron arm fixed to the platform outside the vessel. This arm is composed of five cranks, two of which receive the extremity of the pistons, the three others, articulated by means of double cranks to the levers, serving as a fulcrum in the fluid. Three couples of these levers are suspended from pivots at the exterior extremity of the platform; these act parallel to the course of the vessel, and carry articulated palms, three in number, which reach to the level of the keel, each presenting to the fluid, at the moment of pressure, a surface of two metres square. After each impulse forwards, these palms close of themselves to return, and open again only to give the next impulse.

"The cranks of the pistons being fixed according to two planes, each at a right angle with the other, the moving force is nearly equally distributed during one evolution of the articulated arm; but, by the arrangement of the double cranks which communicate to the articulated palms, each of these exercises its pressure upon the fluid during only one-third of the evolution, and the maximum of this pressure takes place in a very short space of time the remaining two-thirds of the evolution are taken up in the return and in the opening of the palms.

"Although the technicality of the above description may render a conception of the new invention rather difficult at first sight, its effects may be easily conceived by imagining the backward and forward motion of two webbed palms, propelling a vessel forwards, one palm opening and moving parallel to her course, whilst the other, having performed its functions, closes by the pressure of the fluid acting on the articulations, and returns to its place in a direction opposite to the vessel's course, again to advance when its companion is on the point of returning, having in its turn performed its office."

ACADEMY OF SCIENCES.

Dec. 20.—Announcement was made of the completion of the great Geological Map of France, by Messrs. Dufrenoy and Elie de Beaumont. It was commenced in 1823, under the direction of the late M. Brochant de Villiers; eleven years were occupied in geological researches *in loco*, and the other seven years in the classification of materials, in drawing, engraving, &c. The map, divided into several sheets, is now published, with a volume of descriptive letter-press.

A report was read on the works undertaken by Dr. Fontan and M. François, engineer, for improving the thermal sources at the Bagnères de Luchon, in the Pyrénées. By driving horizontal galleries into the rock, near the old mouths of the sources, they had succeeded, not only in obtaining water in great quantity, but also of greater heat. Some of the old springs have dried up in consequence, but the general improvement of the springs was very great, and it had been accomplished at a cost of only 30,000fr. The works lasted two years.

A series of observations and questions was addressed to the Academy, from the Minister of Marine, on the natural history of the silk-worm, with propagating the growth of silk in the West Indies. M. Perottet had been sent out to examine into the best means of promoting this object. This gentleman had remarked that silk-worms' eggs carried to the West Indies from France, and kept in those hot countries for seven or eight years, could not be hatched until the end of eight or nine months, notwithstanding the high temperature, and then only at long and irregular intervals; but when the same eggs were put in an ice-house for four or five months, they were hatched within ten days from their being exposed to the circumambient atmosphere, and nearly all at once. Directions for the proper treatment of worms under these circumstances were demanded of the Academy. The subject was referred to the Section of Rural Economy.

The greater part of this day's sitting was occupied with the reading of medical and anatomical papers.

THE RIVER CLYDE NAVIGATION.

In the "*Glasgow Argus*," of the 6th ult. we find an address presented to the Owners of the Steam Boats on the River Clyde, to the Trustees; wherein is mentioned that the steamers on the River Clyde carrying passengers have competed most successfully with the New Railway running parallel with the Clyde, from Glasgow to Greenock. The following is an abstract of the address.

GENTLEMEN—The first season since the opening of the Greenock Railway having terminated, we beg to apprise your honourable Board of the comparatively great and almost unlooked-for success which has attended the River traffic during the summer months, notwithstanding the formidable opposition we have had to encounter, in our novel and confessedly powerful competitor. * * * We beg specially to express our gratitude for the invaluable boon conferred on us, in authorising the river steamers to arrive at and depart from the New Wharfs, adjoining the Glasgow Bridge, and which we have no hesitation in stating has been the means of *entirely saving* our River trade! * * * Seeing the resolution by which this grand measure has been effected was passed unanimously at your Board, we feel that it would be almost invidious to particularize any individual as being more serviceable than another in carrying that resolution into practice. Yet, while we know that we are deeply indebted to every member of the Trust individually, we cannot close this address without adverting in marked terms to the great exertions and personal sacrifice made by James Hutchison, Esq., as contributing in a very eminent degree to the success of the new arrangements. The almost daily attendance of this gentleman at the new wharfs for a considerable period about the time of their opening, striking evinced the warm interest he felt in the object for which they were erected. We would beg most respectfully also to notice the unremitting diligence, and skilful co-operation of your invaluable river engineer, Mr. Bald. The care and attention with which he studied the working of his plan in all its bearings,—carried into effect whatever suggestions he judged likely to be useful, and in every possible way devoted his time and his talents to the furtherance of this new undertaking.

are above all praise, and will not soon be forgotten by any of our number. It is not for us to hazard any opinion as to the egregious folly of laying a line of rails along the margin of such a noble and magnificent river as the Clyde. We only know that, with your continued co-operation and support, we have nothing whatever to dread from any such uncalled-for competition. On the contrary—confident of success as heretofore—we can now fearlessly bid defiance to this new rival conveyance, with all its boasted advantages, and have no doubt that the Clyde, in every branch of its traffic, shall still as powerfully as ever contribute to the prosperity of Glasgow!

MISCELLANEA.

Lake of Como.—In the *Eco della Borsa* of Milan, there is an account of an experimental trip, made on the 15th November last, of the iron steam boat *Sirius*, constructed for and under the superintendence of Mr. B. Albano, C.E., of London, for the navigation of the Lake of Como. She is 105 tons burden, and was built in England by Messrs. Ditchburn & Mair, and fitted with a pair of beam engines of only 16 horses power each, by Messrs. Rennie. The following account is taken from the report of M. Caronti of Como (agent to the Steam Boat Company) to the directors at Milan. After a minute examination of the boat and engines by M. Albano, who made the required arrangements for a trial, the boat left the Olmo and arrived at the point of the town of Torno, a distance of 5 miles, in 25 minutes, and in 5 minutes more it reached the Pliniana with a strong head wind, and returned direct from the point of Torno to the port of Como in 20 minutes. At the first experimental trip made on the 14th of October last, with the directors and a party on board of above 100 persons, the boat performed then a journey from Como to Domaso, a distance of more than 30 miles, in 2 hrs. 40 min., and from Domaso to Como in 2 hrs. 35 min., the engines making from 37 to 39 strokes per minute, and the boat remaining very steady in the water. With such small power this boat has done wonders, and it will prove a great desideratum to the travellers on the Lake, who have been used to travelling by the old steam barge, running at a speed of only 4 miles per hour.

Ireland.—A Presbyterian church has been erected at Portaferry, on the site of the former edifice, from the designs, and under the immediate superintendence of Mr. Millar, architect. The difficulty of the site (being a piece of sloping ground, at least 10 feet in 100) with which he had to contend, has, in this instance, been changed into a positive and original beauty, such as does not exist in any public building that we are acquainted with in the three Kingdoms. The first story, or body of the house, as it is usually termed, is contained in a stylobate, eleven feet high, or massive pyramidal basement, off which rises the columnar edifice. The lower portion of the building is entered from the south end, through a vestibule on the same, or lower level, on which this stylobate rests. On the north end, the stylobate returns east and west, forming an elevated terrace level with the back gallery entrance, and a higher part of the street, thus giving space large enough for a carriage to turn with ease, at the north propylæum, which presents a front of six elegantly proportioned and massive Doric columns. The intercolumniations of the four centre ones, and returns to their ante, are filled up to about one third of their height with thin freestone slabs of large superficial extent, reaching from column to column; the remaining two-thirds being filled with glazed cast metal ashes of an exceedingly light description; thus giving, by this simple, though unique expedient, the great advantage of seeing the columns, internally as externally, which, by their unadorned finish, give the whole edifice the effect and proportion of simple, yet classic beauty. In a parallel line to these, at nine feet farther back, stand Ionic columns in antæ, sustaining a vast beam, forming a marginal line to the ceiling of the house, which is richly coffered; the four angular coffers being filled with ornamental ventilating centres of elaborate workmanship, and chaste design. At the south end a similar screen extends from column to column, separating the vestry from the body of the church, against which is placed the pulpit, in form of the ancient rostrum, supported on massive scroll trusses, projecting from the wall, and finished in Siena marble, so as to harmonize with the galleries and its ante in colour, it being part and parcel of the general design, connecting them from right to left.

The style of architecture which Mr. Millar has adopted for the very peculiar site, is that which prevailed in Greece during the architectural age of Pericles; its dimensions are sufficiently large to produce an impression of grandeur and sublimity, which is not disturbed by any division of parts; and whether viewed closely, or from the opposite shores of Strangford, there is nothing obtrusive to divert the mind of the spectator from contemplating the unity, as well as the majesty of mass and outlines—circumstances which form the first and most remarkable characteristics of the great prototypes erected during the purer age of Grecian art, on which the architect has evidently founded his studies; thus stamping his works, where they have been carried out under his own eye, with perfection and harmonious beauty, without stooping to the factitious aid of adventitious embellishment. We would fain hope that such buildings as this, erected from the designs of a professional man, may serve as a stimulant in directing public attention to this too much neglected subject, and particularly in rousing the self-esteem of members of all religious establishments.—*The Downpatrick Recorder*.

King's College.—Mr. Hoskings, on Tuesday, the 25th ult., delivered his introductory lecture on the principles and practice of architecture, in which he dwelt at length upon the importance of attending to construction, and concluded by offering some advice to the architect on making competition designs.

Woolwich.—On the 3rd January, the master shipwrights, Mr. Oliver Lang, of Woolwich dockyard, Mr. John Fincham, of Chatham dockyard, Mr. James Atkins, of Sheerness dockyard, Mr. Richard Blake, of Portsmouth dockyard, Mr. Thomas F. Hawkes, of Plymouth dockyard, and Mr. Roberts, late of

Devonport dockyard, assembled at Woolwich dockyard to decide upon the plans which it would be most desirable to adhere to in future, as a fixed principle for building vessels for Her Majesty's navy. This resolution on the part of the Admiralty will prevent all chances of difference of opinion on such matters, and prevent the possibility of the work of one master shipwright being altered or condemned when the vessel is sent to any other dockyard than the one where she was constructed for repair, which has sometimes been the case on former occasions. One fixed principle of ship-building at all Her Majesty's dockyards will be attended with very beneficial results to the service, and it would be advantageous were the master shipwrights to meet annually, or oftener, to take into consideration such discoveries as might be made owing to the present advanced state of scientific knowledge.

French Line of Steam Ships to New York.—France and the United States are to be more nearly allied by a line of steamers. The *Courrier des Etats Unis* says that M. D'Aubigny, captain in the French navy, recently arrived at New York, had been sent thither by the Minister of Marine, for the special purpose of investigating the actual condition of steam navigation in the United States, and of studying the improvements that have been made. M. D'Aubigny is of opinion, that the close of 1842 may be assigned as the time at which a first line of four steam-packets, between Havre and New York, may be put in operation. Vessels it is said, are already in a forward state of progress, of the war model, but so constructed as to serve admirably, in time of peace, for the transport of goods and the conveyance of passengers. They will be commanded by officers of the navy, as the English vessels are. Their capacity is to be about 1200 tons, and their power 500 horses. M. D'Aubigny will set out, in a few days, for the south, whose principal rivers and seaports he will examine. He has given minute attention to the steam frigates *Missouri* and *Mississippi*, at the Navy yard on Long Island.—*New York paper*.

The Steam Engine.—M. Delcruze has lately made a discovery among the manuscripts of Leonardo da Vinci, carrying back a knowledge of the steam-engine to at least the 15th century. He has published, in the *Artiste*, a notice on the life of Leonardo da Vinci, to which he adds a fac-simile of a page from one of his manuscripts, and on which are five sketches with the pen, representing the details of the apparatus of a steam-gun, with an explanatory note upon what he designates under the name of the "Architonnerre," and of which note the following is a translation:—"Invention of Archimedes.—The Architonnerre is a machine of fine copper, which throws balls with a loud report and great force. It is used in the following manner:—one-third of this instrument contains a large quantity of charcoal fire. When the water is well heated, a screw at the top of the vessel, which contains the water, must be made quite tight. On closing the screw above, all the water will escape below, will descend into the heated portion of the instrument, and be immediately converted into a vapour so abundant and powerful that it is wonderful to see its fury and hear the noise it produces. This machine will carry a ball of a talent in weight." It is worthy of remark, that Leonardo da Vinci, far from claiming the merit of this invention for himself, or the men of his time, attributes it to Archimedes.—*Gulligan's Messenger*.

The Milan and Monza Railway.—We have seen a report from Mr. Scott, the locomotive engineer of the railway, to Mr. Albano, C.E., who is superintending the construction of the locomotive engines in the country for the above railway, stating "that no engine that he had yet seen at all approached the locomotive engine 'Lambro,' in any respect whatever; in the economy of fuel, in her immense dragging power, and in the excellency and the solidity of her framing, and working gear." This engine was built by Messrs. G. and I. Rennie, under the directions of Mr. Albano. She has cylinders 13 in. diameter; 18 in. stroke; 5 ft. 6 in. driving wheels; weight 22 tons; average pressure 50 lb.; average velocity 36 miles per hour; weight drawn 143 tons. She commenced running on the 24th June last. The following account shows the very small quantity of fuel consumed each journey:—

June 24, 1841.	140 miles,	coke consumed	5612 lb., or 40lb. per mile.
" 29,	140 "	"	4612 " 33 "
Sep. 8,	180 "	"	3900 " 22 "
Nov. 1,	120 "	"	2634 " 22 "

Palmer's Patent Electrotint.—We have just seen some proofs printed from plates prepared by a process for which Mr. Palmer, of Newgate-street, has taken out a patent. The proofs which we have seen are a dog's head, by Mr. T. Sampson; a study of a head by Wilkie, by Mr. T. Sampson; a fisherman, sketched by the same artist; and a fruit piece by Mr. G. Lance. This method of preparing copper plates and obtaining printed copies is called "electrotint;" and the following description of it, in the words of the inventor himself, will best explain its nature and capabilities of application. "The name of 'Electrotint' is given in distinction from 'Electrotype' to this invention, the latter being produced from engraved plates, whereas the electrotint plates are deposited, by the electrotype process, upon paintings made by artists upon a white metallic surface, with a composition resembling black paint. In the white portions of the design the surface is left uncovered, and the composition used sparingly in the middle tints; but where dark or black portions occur, it is laid on thickly and roughly.—The electrotint plates will of course be covered with indentations corresponding with the projections of the composition, which will receive the printing ink in proportion to their depth, and convey it in printing to the paper. The above plan is reversed to apply to printing from raised surfaces, such as wood blocks. A smooth black surface is chosen, and a white composition laid on with a stiff brush, &c. All those portions where the black surface is made to appear through the composition will, in the electrotint plate, project sufficiently to receive the ink from the printing roller, and transfer impressions to paper." It will be seen that artists, by adopting this method, can transfer to the copper or wood-plates, and thence to paper, copies minutely correct of their own peculiar styles of handling, and, as it were, rivet indelibly facsimilia of the spirit of their original compositions. The four prints we have seen are exceedingly beautiful; they are clear and brilliant, and free from that appearance of soot in the shadows by which lithographic prints, &c., are occasionally disfigured.

The new invention is yet in its very infancy, but from what it has already developed of its powers, it may be safely foretold that it is likely to attain a speedy and a lasting maturity in the history of the fine arts.—*Times*.

Preservative for Water colour Drawings and Engravings.—Mr. Spilisbury, of Pall Mall, has invented a solution for washing over water colour drawings and engravings, which preserves them from the action of the atmosphere, and at the same time allows them to be washed the same as an oil painting, a great desideratum; it is deserving of a trial by those who wish to preserve their engravings, without going to the expense of plate glass.

Ede's Portable Chemical Laboratories.—They are very compact cabinets, fitted with a great variety of tests and re-agents, glass tubes, blow pipes, and other appendages necessary for performing numerous experiments.

OBITUARY.

DIED, on Thursday, the 13th ult., at his residence, near Plymouth, J. Foulston, Esq., M. I. B. A., aged 69. The death of Mr. Foulston cannot fail to excite a melancholy interest, in these towns and their neighbourhood, with which his name as an architect is almost as much connected as that of Wren with the city of London. Before his arrival among us, we had been for centuries in darksome ignorance, as to the meaning and merits of architecture. The success of Mr. Foulston, in his competition for the Royal Hotel and Theatre, fortunately established him as our resident architect; and his subsequent labours for many years were directed to the improvement and adornment of the three towns, naturally promoting that advance of the public taste, which is now manifesting itself in a general feeling for the "beautiful." The simple magnificence of our Hotel exterior, majesty of the Portico to the Devonport Town Hall, and the classic elegance of the Athenæum, and Plymouth Library, bear ample testimony to the distinguished merit of Mr. Foulston, as a disciple of the Grecian school; while his ability and taste in treating the other varieties of design are shown in the Gothic Chapel of St. Paul, Stonehouse, and the Egyptian and Moorish buildings of Ker-street, Devonport. The monumental column in the latter town is also a pure and striking example of the architect's feeling for Greek simplicity. And we would suggest that this especially should be individualized as his monument, by an inscription to his honour, cut on a brass or marble alab, and let into one of the panels of the pedestal. Mr. Foulston was buried in St. Andrew's New Cemetery, on Tuesday, the 18th ult.—*Plymouth Paper*.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 24TH DECEMBER, 1841, TO 27TH JANUARY, 1842.

Six Months allowed for Enrolment.

WILLIAM ROBINSON KETTLE, of Waterloo-street, Birmingham, Warwick, accountant, BENJAMIN WAKEFIELD, of Ryland-street, North, Birmingham, civil engineer, and WILLIAM CROSHER, of Cumberland-street, Birmingham, aforesaid, screw manufacturer, for "an improved bolt for building, and other purposes."—Sealed 24th December.

MONTAGU MACDONOUGH, of St. Alban's-place, Middlesex, gent., for "improvements in spindles, flyers, and bobbins, for spinning, twisting and reeling all sorts of fibrous or textile substances, and in the application or adaptation of either, or all of them, to machinery for the same purposes." (A communication.)—Jan. 6.

EDWARD HALL, of Dartford, civil engineer, for "an improved steam boiler."—Jan. 11.

SAMUEL HEARNE LE PETIT, of St. Pancras-place, St. Pancras-road, for "certain improvements in the manufacture and supply of gas." (A communication.)—Jan. 11.

JAMES CHESTERMAN, of Sheffield, mechanist, and JOHN BOTTOM, also of Sheffield, aforesaid, mechanist, for "certain improvements in tapes for measuring, and in the boxes for containing the same."—Jan. 11.

CHARLES WYE WILLIAMS, of Liverpool, gent., for "improvements in the construction of furnaces, and effecting combustion of the inflammable gases from coal."—Jan. 11.

JOHN TRESAHAR JEFFREE, of Blackwall, engineer, for "improvements in lifting and forcing water and other fluids, parts of which improvements are applicable to steam engines."—Jan. 11.

RICHARD DOVOR CHATTERTON, of Derby, gent., for "improvements in propelling."—Jan. 11.

JAMES IONS, of Newcastle-upon-Tyne, gent., for "improvements in smelting copper ores."—Jan. 13.

JULIUS BORDIER, of Austin Friars, merchant, for "improvements in preparing skins and hides, and in converting them into leather."—Jan. 13.

CALEB BEDELLS, of Leicester, manufacturer, and JOSEPH BEDELLS, of

the same place, assistant to the said CALEB BEDELLS, for "improvements in the manufacture of elastic fabrics, and articles of elastic fabrics."—Jan. 13.

JOSEPH BARNES, of Church, near Accrington, Lancashire, manufacturing chemist, for "certain improvements in the working of steam engines."—Jan. 13.

HENRY WATERTON, of Winsford Lodge, Chester, Esq., for "improvements in the manufacture of salt."—Jan. 13.

JOHN JEREMIAH RUBERY, of Birmingham, umbrella and parasol furniture manufacturer, for "improvements in the manufacture of a certain part of umbrella and parasol furniture."—Jan. 13.

MOSES POOLE, of Lincoln's-inn, gent., for "improvements in the construction of locks." (A communication.)—Jan. 15.

JOHN THACKERAY, of Nottingham, lace thread manufacturer, for "improvements in the process of preparing and gassing thread or yarn."—Jan. 15.

THOMAS LAMBERT, of Regent's-park, musical instrument maker, for "improvements in the action of cabinet piano-fortes."—Jan. 15.

EDWARD PALMER, of Newgate-street, philosophical instrument maker, for "improvements in producing, printing, and embossing surfaces."—Jan. 15.

JAMES COLE, of Youl's-place, Old Kent-road, brush manufacturer, for "improvements in the construction of brushes."—Jan. 15.

CORNELIUS WARD, of Great Titchfield-street, musical instrument maker, for "improvements in flutes."—Jan. 18.

WILLIAM TINDALL, of Cornhill, ship owner, for "a new and improved method of extracting or manufacturing from a certain vegetable substance, certain materials, applicable to the purposes of affording light and other uses."—Jan. 19.

ANTOINE MERTENS, of the London Coffee-house, publisher, for "improvements in covering surfaces with wood." (A communication.)—Jan. 22.

WILLIAM BAKER, of Grosvenor-street, Grosvenor-square, surgeon, for "improvements in the manufacture of boots and shoes."—Jan. 27.

JOHN JAMES BAGGALY, of Sheffield, seal engraver, for "improvements in making metallic dies and plates for stamping, pressing, or embossing."—Jan. 27.

ANDREW KURTZ, of Liverpool, manufacturing chemist, for "improvements in the manufacture of artificial fuel."—Jan. 27.

FRANCIS MARSTON, of Aston, in the county of Salop, Esq., for "improvements in apparatus for making calculations."—Jan. 27.

SAMUEL MASON, of Northampton, merchant, for "improvements in clogs, —part of which improvements is applicable to shoes and boots."—Jan. 27.

GOTTLIEB BOCCIUS, of the New-road, Shepherd's Bush, Gent., for "improvements in gas, and on the methods in use, or burners for the combustion of gas."—Jan. 27.

WILLIAM and JOHN GALLOWAY, and JOSEPH HALEY, of Manchester, engineers, for "improvements in machinery for cutting, punching, and compressing metals."—Jan. 27.

PIERRE JOURNET, of Dean-street, Soho, engineer, for "improvements in steam engines." (A communication.)—Jan. 27.

HENRY BENJAMIN, of St. Mary-at-Hill, fish factor, and HENRY GRAFTON, of Chancery-lane, machinist, for "improvements in preserving animal and vegetable matters."—Jan. 27.

TO CORRESPONDENTS.

The American Pile-driving machine.—We neglected to mention in our last number, that this machine had been patented in this country, as well as on the Continent, by Col. Cowdin and others. We have received two communications on the subject of the table on the force of falling bodies, questioning the accuracy of the formulæ upon which the calculations were made. These communications we have deferred until next month, in order that we may in the mean time make some practical experiments on the force of falling bodies, which appears up to the present time to have been neglected by all our mechanical writers.

Bunnett's Patent Railway Breaks and other improvements.—We had intended to have given drawings and descriptions of these in the present number, but we have been prevented, in consequence of the wood engraver not being able to get the cuts finished in time.

J. M. on Architectural Precedent will appear next month.

We shall be glad to hear again from "Oliver Twist."

Sandstone.—We will notice his communication in the next Journal.

Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," No. 11, Parliament Street, Westminster.

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, III, and IV, may be had, bound in cloth, price £1 each Volume

ERRATA.

In Mr. Weale's advertisement of last month, the price of Buchanan's Mill work was printed 2l. 5s. instead of 2l. 10s.

On the Use of Gold for Decoration, page 7, line 7 from bottom, for *finely paid*, read *firmy fixed*.

MAPLIN SAND Lighthouse.

South Elevation.

*Light 45 Feet above the mean Level of the Sea
first exhibited on the night of the 10th Feb^r 1841.*

Scale 0 10 20 Feet.

THE MAPLIN LIGHTHOUSE.

ENGINEERS, MESSRS. WALKER & BURGESS.

(With an Engraving, Plate III.)

In the second volume of the Journal, page 38, we announced the commencement of this lighthouse, and at page 132 of our last volume, we had the pleasure to notice its completion. We then gave some account of its construction, to which we must now refer our readers. The lighthouse, since its completion in October, 1840, has stood the test of several severe gales, and is at this day as firm as when first erected. Coupling this with the equal success of the Fleetwood lighthouse, it is in our opinion an indubitable proof of the utility of the screw pile system, and of the resources which it presents to the engineer in the construction of lighthouses on sands, in the place of floating beacons as now adopted, which are so apt to drive from their moorings in stormy weather, and which then produce such disastrous consequences.

The annexed engraving is a correct view of the lighthouse, and clearly shows its construction.

PEN AND PENCIL SKETCHES IN POITIERS AND
ANGOULÊME: WITH SOME REMARKS ON EARLY
ARCHITECTURE.

By GEORGE GODWIN JUN., F.R.S., &c.

Chapter 1.

POITIERS, the *Limonum* of the Romans, and present capital of the department of Vienne, is nearly two hundred miles from Paris, on the road to Bordeaux. It is memorable as the field of three of the most important battles recorded in the annals of France; by two of which, at all events, the progress of society was materially affected.* The Gauls, the Romans, the Vandals, the Visigoths, the Franks, the Normans, and the English, have alternately held dominion here, and have left their impress on the soil, or in the customs of the people. To the passing traveller, Poitiers, ill-built and mean in appearance, seems hardly to offer sufficient inducement for a stay, giving no evidence at first sight of the many singularly interesting remains of ancient skill which it possesses. It is in all respects an *old town*,—a *bye-gone thing*,—and takes one back to times when society had not educated itself into so many wants as now, and men cared little for their own habitation, but raised magnificent temples to God. To the antiquary, the architect, the student in history,—in fact to all inquirers,—Poitiers will afford a harvest of information, and be fruitful of suggestions: moreover, being situated on a hill, at the confluence of two rivers, it commands some pretty country, and becomes in itself a picturesque object, when viewed from a distance.

The Gauls have left but one monument in the neighbourhood of Poitiers. It is called there the *pierre levée*, and is considered by archaeologists to be either a tomb or a Druidical altar. It is said to be a block of calcareous stone, 22 ft. 3 in. long, 15 ft. wide, and 2 ft. 9 in. in mean thickness. In form it is a lengthened oval, pointing south-east and north-east, raised 3 ft. 4 in. from the ground at one end only, the support at the north-eastern end, if there ever were one, having been removed.† It is hardly necessary to remark, that many marvellous stories are told touching the origin of this stone; but with these we may not meddle.

The remains of an amphitheatre at Poitiers, sufficiently large to accommodate more than twenty thousand persons, show clearly the

* In the sixth century Alaric, king of the Visigoths, was defeated here by Clovis; in the eighth century the Saracens, under Abd-el-rahman, were vanquished by Charles Martel; and in the fourteenth century Edward the Black Prince gained here his great renown.

† "Mémoires de la Société des Antiquaires de l'Ouest."

importance of the town in the Roman times. It is supposed to have been built in the third century, and considerably exceeded in size both that of Pompeii and of Nîmes. The various ranges of steps, divided by corridors and staircases, are still to be traced, as well as a large arched vault, 18 or 20 feet wide, and 60 or 70 feet long, (formed of rough flat pieces of stone, and mortar, now like a rock,) which inclining rapidly, opens from the outside into the arena, and afforded entrance to the wild beasts, or the little more civilized gladiators.

The most ancient, and at the same time most interesting building in Poitiers is known as the temple of *St. Jean*. The origin and date of this very curious structure have afforded matter for many disquisitions, and have been the cause of much controversy amongst the French antiquaries. Some believe it to have been a Roman temple, others a tomb erected at the end of the third or beginning of the fourth century, in memory of Varenilla, a Roman lady, to whom the city voted a statue and public monument; while a third set of writers, amongst whom is the Abbé Leboeuf, consider that it was, even originally, a Christian church, in the erection of which the materials of some pagan temple were used. From the discovery of an octagon excavation beneath the pavement of the edifice, strengthened by tradition, it is further supposed that it served as a baptistery as well as a chapel. M. de Caumont, who inclines to this opinion, considers the peculiar form of the building is accounted for by its double destination.

Fig. 1.

The accompanying sketch, fig. 1, shows the plan of what is supposed to be the original building, in form a long square, measuring about 30 ft. by 42 ft., with an absis at the north-east end, raised one step above the main apartment, and measuring about 16 ft. by 18 ft. In the opposite wall are three lofty arched entrances, beyond which is a vestibule of more modern, although still ancient, construction, being probably of the eleventh or twelfth century. The floor of the building is several feet below the street level.

Sketch No. 2 represents the general appearance of the north-east end of the building, and although slight, will enable the reader more easily to comprehend the description. The walls, about 45 ft. in height, are divided into two stories, the uppermost of which contains two arched openings, with small columns at the angles, and a triangular-headed space between, and the lower story, the entrance to the absis. The columns in the lower story are of coloured marble, and were evidently brought from some other building, being mostly different from one another in size and

Fig. 2.

height. The sculptured capitals, which are greatly injured and defaced, indeed, for the most part destroyed, vary in design, and are ill-fitted to the shafts. The capitals of the small columns in the windows are formed of comparatively large flat leaves. The upper story of the two side walls is similar in arrangement to that represented by the sketch, with the exception, that in the latter the triangular-headed opening is wider than it is in the two side walls: in the one case it is about six feet, in the other about three feet six inches. The arches of the windows, (now only circular lights, having apparently been blocked up at some remote period,) and the arched entrance to the absis, are formed of stones about fifteen inches long and three inches wide.

The walls of this building have been covered with paintings or mosaics, many of which still remain. Around the upper part is painted a fret, with birds and other devices on a white panel, in each compartment. The colours in the fret are blue, red, white, and yellow, and have an antique appearance. Over the windows a zigzag line is either drawn in white, or inlaid; and beneath the openings are ornamental scrolls, or other decorations, in colours. On the walls various figures of large size are painted, some few of which have names against them, formed by letters placed one over the other in an upright line: the prevailing colour of the whole is red. The triangular-headed compartment over the absis contains a painted figure of Christ, within a *vesica piscis*, of which mysterious form and its constant recurrence in works of the middle ages, I shall hereafter take occasion to speak.

The soffit of the inner arch leading to the absis is painted; and on the domical ceiling of the absis appears a very large seated figure of Christ or of the Almighty, within a pointed quatre-foil. This has been lately drawn by M. Seguin, for the "Comité Historique des Arts et Monumens," and is described in one of their *Bulletins* to be probably of the thirteenth century: some other figures which surround it appear to be more ancient.

In the absis there is a series of arches and small columns, with capitals closely resembling those of the Corinthian order; one of these is quite so, and the shaft of this displays a slight swell or *entasis*, as is also found in the larger columns at the entrance. Some writers have considered that this portion of the building, like the vestibule, is less ancient than the body of the structure; but this has been warmly combatted, on the ground that the materials composing it and the style employed correspond throughout both. M. Magnon de Lalande is of opinion that the north-west wall, originally similar to that

represented by sketch 2, was altered to its present state when the building was converted into a baptistery, and that the absis in question was constructed at this same time, with the materials of the old wall.*

Fig. 3.

The exterior of one side of the ancient part of the building, both being similar, is represented by sketch No. 3. The upper part of the gable, originally inlaid with glazed bricks or coloured marble in patterns, has been rudely repaired, but still displays a portion of its early adornments. The triangular pediments, as well as the square compartment with a triangular head, contain flat rosettes, formed likewise of glazed or encrusted brick. The semicircular opening in the lower arcade presents a small Greek cross, (by accident not represented in the sketch,) and serves almost to identify the original connection of the building with the Christian religion. The series of corbels below the gable originally bore a cornice, now destroyed. Beneath these, ranges of tiles or thin bricks are seen, alternating with the stones composing the remainder of the front. The pilasters, with their capitals and bases, project but slightly from the face of the wall, and, together with the small entablature which they bear, display very rude workmanship.

On first entering this building, or viewing attentively its exterior, one cannot avoid regarding it as a type of those edifices which we term Saxon and Norman; a most interesting link in that chain which connects the stupendous monuments of Egypt, and the glories of Athens, with the cathedrals of Strasburg, Cologne, or York. In most of those architectural remains in England which are acknowledged to be Saxon, as, for example, the towers of Earls Barton church, Northamptonshire, of St. Peter's church, Barton-upon-Humber, and of Barneck church, Northamptonshire, triangular-headed openings, or straight-lined arches if they may be so called, occur; and they are also to

* "Mémoires de la Société Royale des Antiquaires de France." Tom. xiv. M. Caumont is of opinion there was a similar absis, or small chapel, at the north-west end, before the alteration: this would render the plan of the building cruciform. The same writer is disposed to think the small columns in the windows and the absis are of less ancient workmanship than the larger columns, but that they were worked out of some similar columns, as they are of the same marble. "Cours d'Antiquités." Tom. iv.

be found delineated on some Saxon MSS., by writers of that period. A striking example of these arches may be seen on the entrance to the old monastery at Lorsch, between Darmstadt and Heidelberg, attributed to the end of the eighth century. This pedimental form was often used in Rome for decoration,* when architectural skill and knowledge were declining there, as indeed it was greatly at Constantinople. In the baths of Diocletian, at Rome, columns piled one upon another on either side of window-openings are thus surmounted; and it may likewise be found on many sarcophagi in the catacombs of that same city.

Again, in the Saxon buildings of which we have spoken, small columns are found swelling in the centre, perhaps a rude remembrance of the classic *entasis*; at other times banded in the centre, and so forming a sort of baluster. In more than one of them, too, the Greek cross in circular panels, or over the heads of windows, forms a prominent ornament.

The temple of St. John has experienced many vicissitudes, and has been used at different times as a bell-foundry, a kitchen, and a manufactory. Standing very much in the way of some proposed improvement in the line of streets, it would have been taken down in 1832, had not the "Société des Antiquaires de l'Ouest" vigorously interfered, and ultimately succeeded in purchasing the venerable fabric, which is now occupied by them as an architectural museum. Had the society effected no other good than this, they would merit the gratitude of all admirers of ancient art; beyond this, however, they have done much to elucidate the early history of Poitou and the neighbouring departments, and to induce the preservation of monuments of antiquity.† The destruction of the building in question, which is almost unique, would be a most serious loss, as it could never be replaced or compensated for.

The present cathedral of Poitiers, called *St. Pierre*, was commenced in the year 1154, by Henry II. of England, who held Poitou in right of his wife Eleanor of Aquitaine,‡ but was not completed until 1379. Of the original foundation of the cathedral little seems known. In 1018 the structure which occupied the site of the present church was burnt, and being rebuilt soon afterwards, was again destroyed.

St. Pierre is a cruciform church, of great width as compared with its length, divided into three aisles, and presenting in its western front, seven steps below the street level, three entrance doorways, (over which are a large rose window and two pointed-headed windows,) flanked on either side by an ugly squat tower. In the mouldings around the door-heads are four series of figures; and in the tympanum of the centre opening are sculptured groups, representing Christ surrounded by angels sitting in judgment, the resurrection of the dead, and the separation of the good from the bad,—the latter being thrown into the open mouth of a monster. In the heads of the side doors are represented the death of the Virgin, and St. Peter receiving the keys of Heaven. The whole of this front, with the exception, perhaps, of the lowest story of the towers, is pointed; indeed, very little of the early circular work is anywhere apparent, excepting an attached arcade within side against the north and south walls and in the transepts, and some windows at the east end of the building, the capitals of the columns in which latter are exceedingly curious, being formed of the figures of men in a variety of distorted positions.§ There is some little stained glass in the church: the easternmost window displays a figure of Christ within a *vesica piscis*.

* In earlier times, when the principles of the arch were little if at all understood, this form was used constructively, as in the pyramids of Mexico and Egypt; but to this application we need not refer.

† This Society meets in Poitiers every Thursday during the Session: M. de Darné is the secretary.

‡ Poitou was confiscated to Philip Augustus in the reign of King John (1203); came again into the hands of the English in 1360; and ultimately reverted to France in 1370.

§ A French writer, speaking of this church, observes, "En étudiant les bas-reliefs, depuis celles du chœur construites à la fin du douzième siècle, jusqu'à celles du portail, qui datent de la fin du treizième, on peut suivre la transition du Roman au Gothique, qui s'opérait alors, transition bien marquée dans la forme des fenêtres, dans leurs meneaux, dans les cintres et les ogives qui les décorent; ce qui est une nouvelle preuve de l'usage dans lequel on fut autrefois, lors de ces constructions fort longues, de commencer par l'abside et de finir par le portail."—*Poitiers*: par M. E. V. Foucart.

The interior of this building, although wide and lofty,* has little beauty, and has been much disfigured by modern repairs and additions, —the Antiquaries of *l'Ouest* may here usefully exert their influence, as occasions offer. I cannot avoid mentioning, that the walls of this building both inside and out present on the face of them large numbers of masons' marks, amongst which is the *fish*, and other apparently religious emblems. Several precisely similar marks the writer has found on buildings of much later date in England.†

BUNNETT'S PATENT RAILWAY BREAKS, &c.

MR. BUNNETT, of the firm of Messrs. Bunnett and Corpe of Deptford, has taken out a patent for several important improvements, for the better control of railway trains, and the prevention of accidents. They are simple, cheap, and applicable to the present locomotive engines and carriages; and, if adopted, such a perfect command over the train will be obtained, that it may be stopped within so short a distance as effectually to prevent trains coming into collision with each other, or with obstructions of any kind whatever.

The improvements are as follow:—

I.—A powerful engine break acting upon the upper half of the driving wheels, and also simultaneously on the trailing, or the leading-wheels, and occupying the place of, and forming, the wheel-guards.

II.—Self-acting spring-breaks for carriages and tenders, attached to the buffers, and acting on every wheel in the train, partially or altogether retarding it, as the necessity of the case may be.

III.—A very simple and powerful manual break for carriages, &c. This, and the above breaks, are formed of an elastic material, thereby avoiding the disagreeable jar and noise now so generally complained of.

IV.—A simple and efficient mode of increasing the adhesion of the driving-wheels of the engine to the rails, by instantaneously throwing the whole weight upon them.

V.—Spring axle-guides, capable of adjustment, allowing sufficient play in the boxes for the axles to adapt themselves to any curves, or to irregularities of the road.

VI.—A means of communication between the guards and engine-driver, by an alarm bell on the engine, which is struck by a spring lever, acted upon from any carriage in the train.

VII.—A method of shutting off the steam on the instant that the engine-driver takes his hand off the regulating-handle, thereby preventing accidents that might possibly occur from drowsiness, fits, sudden illness, &c.

In illustration of the value of an efficient system of breaks, we need only subjoin a portion of the evidence of no less an authority than Mr. George Stephenson, as given by him before a select committee of the House of Commons.

Question 1317. You have, of course, devoted much attention to the means of preventing accidents upon railways?—A. I have.

Q. 1320. You have paid much attention to the subject of breaks?—A. I have.

Q. 1321. Do you consider them an important element of safety in railway travelling?—A. Certainly; the most important of anything that can be contrived for the safety of railway travelling. I believe, that if self-acting breaks were put upon every carriage, scarcely any accident could take place.

* The height of the nave is stated to be 96 feet; that of the side-aisles 80 feet.

† To this very curious subject,—the masons' marks of the middle ages,—to which the writer's notice was first given three or four years ago, he has lately directed the attention of the Society of Antiquaries and the Institute of Architects, with the view of obtaining a large collection of the marks for examination and comparison. The "Comité Historique des Arts et Monuments" of Paris have recently invited communications on the subject.

BUNNETT'S PATENT RAILWAY CARRIAGE BREAKS, &c.

Fig. 1.

Fig. 2.

Fig. 3.

Q. 1322. What do you mean by self-acting breaks?—A. Whenever the power is taken off the engine by the engine-driver, it immediately ceases to proceed so fast; all the carriages immediately run towards the engine, with the impetus put into them before the engine was retarded. Every carriage, as it approaches the next carriage, shall apply the breaks itself. Every carriage is brought into the state of a sledge; the rolling motion of the wheels ceases; and supposing that an engine was running on with twelve or fourteen coaches, and that every coach had a breaksmen (that is, twelve coaches and twelve breaksmen), and the whole of them upon the look-out to see if anything went wrong in the engine, to apply the breaks immediately, I conceive that the *self-acting principle is fifty times better*.

DESCRIPTION OF DRAWINGS.

Fig. 1 shows a mode of applying breaks to the engine: *a* is a strong iron carriage for the breaks laying flat against the side framings, bearing on and attached to the centre of the springs, and supported also by sliding freely through a plate or staple bolted to the side frame, to allow for the play of the springs; *b* is a vertical shaft, on the bottom of which is a worm, taking into a worm-wheel, keyed on a horizontal shaft, which passes across beneath the foot-plate; on the same shaft are keyed two pinions *c*, working into two racked sectors or levers *d*; on bringing the levers to the position shown, the break-bands are brought down on the tops of the wheels on both sides of the engine; on giving the handle a contrary motion, the break-bands are lifted into the position shown by the dotted lines. Any elastic substance, or wood segments in an iron box, may be bolted to the underside of the break-bands, if thought desirable.

Attached to the fire-box of the engine is a bell *f*, on which, by an arrangement of spring-levers, a sharp blow, or several blows, can be instantaneously struck by the guards from any carriage in the train, a simple and effectual mode of communication with the chain *g* running along the tops of all the carriages.

Fig. 2 is a side elevation of a railway carriage frame. At one end is a *self-acting* break, proposed to be applied to all the wheels; *a* is a connecting-rod attached to the buffers; *b* is a bell-crank, the axis of which is attached to the side frame of the carriage; *c* is a strong belt of leather, plaited hemp and wire rope, or any suitable material, to the underside of which, if necessary, plates of metal may be rivetted; *d* is a curved spring, to the end of which, and to the bell-crank *b*, the belt *c* is fastened; upon the buffer being driven in, the bell-crank *b* is moved in the direction of the dotted line, and the belt *c* is brought down on the periphery of the wheel, with a force proportionate to the strength of the spring *d*, which, on the buffer resuming its position, takes the pressure of the belt *c* off the wheels.

The other end of Fig. 2 shows a *Manual* break: *e* is a vertical shaft, on the bottom of which is a worm, working into a worm-wheel on a horizontal shaft *f*, and giving motion to a pair of bevil-wheels *g*, one of which is attached to a short vertical shaft, carrying a pinion *h*, which takes into two racks *i i'*, kept in gear by friction-rollers at the back; the ends of the racks are prolonged, and attached to the centres of two bars passing across the carriage, and carrying at each end the bows *k k'* fitted with elastic bands, on boxes fitted with segments of wood or otherwise.

Fig. 3 is an elevation of a railway carriage frame, showing another form of *self-acting* break; *a a* are strong iron rods attached to the centres of two cross-bars *b b*, which are fixed at each end to the back of the buffers; the other ends of the rods *a a* are forked, and pass over a spring *c c*, the ends of the springs impinge against bars *d d*, passing across the carriage, on the ends of which are fixed boxes fitted with segments of wood, or with bows, &c. similar to *k k* in Fig. 2; *f* is a curved stay in the plane of action to the centres of the wheels, on which are formed guides for the ends of the bars *d d*; the springs *c c*, and the bars *d d'*, are shown in section; the rods *a a* are capable of adjustment in the length, so as to bring the breaks into action when the buffers shall have been driven in to any point desired; the action of the breaks on all the wheels is simultaneous, and the force equal to the strength of the springs *c c'*.

It will be perceived, that one advantage in these breaks is the absence of concussion on their being applied, as they are governed by the buffers. More or less force is applied, as more or less occasion exists for the same. Should the strength of the buffer springs be at any time insufficient to admit of the backing of a train, there is a ready mode of preventing the action of the breaks upon the wheels.

SLUICE GATES.

Description of the Bear Trap Sluice Gates of the Lehigh Descending Navigation. By ELLWOOD MORRIS, Civil Engineer.

(From the American Franklin Journal.)

THE public are indebted to the inventive genius of Josiah White, Esq., President of the Lehigh Coal and Navigation Company, for the admirable hydrostatic contrivance which has received the singular name of *Bear Trap*.

These sluice gates were devised in the year 1818 by the "*Lehigh Navigation Company*," for the purpose of improving the Lehigh river by means of wing-dams, &c., so as to form a descending navigation suitable for the transportation of coal from the Anthracite mines, near Mauch Chunk, to the city of Philadelphia.

This work was commenced upon the 10th of August, 1818, and did not originally contemplate the use of sluice gates as a primary expedient; the residents upon the margin of the Lehigh river having pointed out "a certain mark in a rock at the Lausanne landing," as the low-water level of the stream, the Company were induced to believe that there would always be a sufficiency of water for their purposes, if it were "confined by wing-dams in its passage over the ripples, or shoals, from pool to pool," and under this impression the work was begun; but in the autumn of 1818 "the water in the river fell by an unparalleled drought, as was believed, fully twelve inches below the mark which has been mentioned as shown by the inhabitants to be the lowest point to which the river ever sunk. Here was a difficulty totally unanticipated, and one which required a very essential alteration in the plan. Nature did not furnish enough water by the regular flow of the river, to keep the channels at the proper depth, owing to the very great fall in the river and the consequent rapidity of its motion. It became necessary to accumulate water by artificial means, and to let it off at stated periods, and let the boats pass down with the long wave thus formed, which filled up the channels. This was effected by constructing dams in the neighbourhood of Mauch Chunk, in which were placed sluice gates of a peculiar construction, invented for the purpose by Josiah White, one of the managers, by means of which the water could be retained in the pool above, until required for use. When the dam became full, and the water had run over it long enough for the river below the dam to acquire the depth of the ordinary flow of the river, the sluice gates were let down, and the boats, which were lying in the pools above, passed down with the artificial flood."

It was to meet the exigency created by the discovery above-mentioned, that Mr. White contrived the beautiful sluice gate, which we are about to describe, and upon the successful operation of which the whole enterprise very much depended.

At that day the scene of the Company's operations was almost a perfect wilderness, and the carpenters having been set at work to frame a sluice gate for trial, it became an object of great curiosity to the settlers; who being far more familiar with the implements used in the chase and capture of the beasts of the forest, than with the hydraulic works of a flash navigation, either in jest, or from some fancied resemblance of the sluice gate to a *Bear Trap*, quickly gave to it this cognomen, which it ever since has borne.

A, Upper leaf of sluice. B, C, D, Water chambers. E, F, Wickets. G, Cribwork. H, Pool of dam. I, Plank floor. J, Fingers of timber. W L, Water line.

The *Bear Trap Sluice Gate*, which is exhibited in plan and section in the annexed diagrams, consists of two leaves or shutters, reclining against each other so as to present a triangular vertical section, and contain beneath them a space capable of being filled with water from the superior level, and emptied thereof at will; the contained angle at the vertex, when the gates are up, being rather more than 100° , in order that the leaves may slide easily, one over the other, which they evidently would not do if the vertical angle of the uplifted gate were either a right or an acute angle; this sluice gate is raised and depressed by hydrostatic pressure, applied and removed upon the principle of that well known philosophical instrument called the Hydrostatic Bellows; in its usual form, as applied upon the Lehigh, it *will not work in dead water*, but requires the action of a head more than sufficient to overcome the weight and friction of the gates, to enable it to be manœuvred with facility.*

By an inspection of the diagrams it will be perceived that the leaves

* Mr. English, formerly a contractor upon some of the works of the Lehigh navigation, having for many years observed the action of the Bear Trap Sluice Gates, has conceived the idea of rendering them applicable as the upper gates of *Lift Locks*, by placing a large air vessel under the lower leaf, which by its buoyancy enables the gates to rise in dead water: and he has exhibited at the Franklin Institute a working model of a lock having the Bear Trap Gates, with his attached air vessel applied as *upper gates*; and, though liable to some objections, there is reason to believe that for the upper, if not for both, gates of *Lift Locks* only, they will prove to be a valuable improvement, though it is evident that the same object may be attained by the application of counter weights, but not perhaps as well as by an air vessel

of the gate are hinged horizontally with hollow quoin joints, at some distance above the floor: the hinge of the upper leaf being higher than that of the lower, by something more than its thickness, so that even when the gate is down there is a vacant space into which the aperture opens from the well C, because the height of the hinge of the lower leaf is fixed at about the same level as the tops of the openings communicating with the well.

Catch blocks on the under side of the upper leaf A determine the height to which the rise of the gate is limited; the well C is constantly in communication with the vacancy beneath the gate; the water chamber B, is constantly open to the water from the upper level, whilst that of the lower level flows freely into the chamber D; it will be observed that both these chambers communicate by suitable wickets E, F, with the well C; now it will be evident from inspection that if the wickets F, between C and D are shut, whilst the wickets E between C and B are opened, the water from the upper level will enter beneath the leaves with the *upward* hydrostatic pressure due to the head, and the gate will consequently rise. Now, on the other hand, if the wickets E are closed, whilst those at F are opened, the *downward and lateral* hydrostatic pressure of the water in the upper level, acting then upon the top surface A of the upper leaf, will force down the gate; and thus by simply putting the vacancy beneath the leaves of the sluice gate, in communication *separately* with the upper and lower levels *alternately*, the gate is elevated, depressed, or arrested at any stage of its movement, by hydrostatic pressure alone; the only manual labour or

attention needed for the highest and widest gates, being that which is requisite to manœuvre the wickets E or F, a duty for which a mere boy would be physically competent.

The sluice gates used upon the Lehigh descending navigation, as there is no necessity of making them perfectly water-tight, are allowed a play on each side of half an inch or more, which effectually prevents lateral friction; they are generally twenty-four feet wide, formed by spiking together three successive layers of thick plank, and the lower leaf is strengthened by bolting upon its back a few heavy beams, (as may be seen in the sketch annexed,) which rest their extremities against suitable stops when the gate is up.

Where the water, violently descending the sluice, leaves the platform, it usually excavates the bed of the stream and forms deep water, the sudden entrance into which, of boats shooting down the sluice, would prove very injurious to, or even destroy them, if it were not for the ingenious device called *fingers*; these consist of the trunks of trees placed side by side, and bolted to heavy subsills, with their butts up-stream, the tops freely projecting over the lower sill some twenty feet or more; they receive in part the shock of the boat in its plunge into the deep water, and by their elasticity ease off its momentum so that it glides down with the swift stream uninjured. This dexterous mode of avoiding concussion is found in practice fully to answer the end for which it was designed.

For the purpose of guarding the horizontal hinges of the leaves of the sluice gates against obstruction from the deposition of gravel, a glove of plank is ingeniously secured across the hinge by a curved spring; and in contact with this plank glove, the leaf revolves upon its hinges, without the possibility of being impaired in its action by the lodgment of hard substances.

From the above description and the annexed sketches, which are designed more to develop the principle of the sluice gate, than to display all the details of its construction, it is hoped that the plan and mode of action of the *Bear Trap Sluice* may be gathered without further explanation, and we will now proceed to make a few remarks upon the great usefulness of this invention.

UTILITY OF THE BEAR TRAP SLUICE.

This skilfully devised hydraulic machine continued in use upon the lower Lehigh—giving perfect satisfaction in practice—from the year 1821 until 1829, when the descending navigation upon the main part of the river was abandoned for an improvement which admitted of transit in both directions: though a section upon the former plan, with its Bear Trap Sluices, still forms the navigation for the lumber trade between Whitehaven and Stoddartsville, a distance of 12½ miles, in which by wing-dams, channels, and sluices, a fall of 336 feet is overcome.

The causes which led to the substitution of a slackwater for a flash navigation, and the difficulties met and surmounted by the ingenious and energetic individuals who directed the works of the Lehigh Company, are so interesting, that we will make a digression to quote a few more passages from the Company's published "History,"*

"The boats used upon the Lehigh descending navigation consisted of square boxes, or arks, from 16 to 18 feet wide, and 20 to 25 feet long. At first two of these were joined together by hinges, to allow them to bend up and down in passing the dams and sluices, and as the men became accustomed to the work, and the channels were strengthened and improved as experience dictated, the number of sections in each boat was increased, till at last their whole length reached 180 feet. They were steered with long oars like a raft. Machinery was

* In the published history from which we quote, the opinion is advanced, that "the descending navigation by artificial freshets on the Lehigh, is the first on record as a permanent thing."

This, however, is a mistake. For the system of rendering shallow streams navigable by the mode called *Flashing*, which is "to create an artificial flood for a time, by penning up the water in the river itself," and then opening the sluice or flood-gates, when the boats are passing, is supposed to have been invented by the Egyptians after the time of Alexander, and was found in use in the hydraulic works of the interior of China, when that empire was visited by the first English embassy.

See New Edinburgh Encyclop., Art. Nav. Inland.

devised for joining and putting together the planks of which these boats were made, and the hands became so expert that *five men would put one of the sections together and launch it in forty-five minutes*. Boats of this description were used on the Lehigh till the end of the year 1831, when the Delaware division of the Pennsylvania Canal was partially finished. In the last year, 40,966 tons were sent down, which required so many boats to be built, that, if they had all been joined in one length, they would have extended more than *thirteen miles*. These boats made but one trip, and were then broken up in the city, and the planks sold for lumber, the spikes, hinges, and other iron work being returned to Mauch Chunk by land, a distance of eighty miles.

"The great consumption of lumber for the boats very soon made it evident that the coal business could not be carried on, even on a small scale, without a communication by water with the pine forests, about 16 miles above Mauch Chunk, on the upper section of the Lehigh. To obtain this was very difficult. The river in that distance had a fall of about 800 feet, over a very rough, rocky bed, with shores so forbidding, that in only two places above Lausanne had horses been got down to the river. To improve the navigation it became necessary to commence operations at the upper end, and to cart all the tools and provisions by a circuitous and rough road through the wilderness, and then build a boat for each load to be sent down to the place where the hands were at work, by the channels which they had previously prepared. Before these channels were effected, an attempt was made to send down planks singly, from the pine swamps, but they became bruised and broken by the rocks before they reached Mauch Chunk. Single saw-logs were then tried, and men sent down to clear them from the rocks as they became fast. But it frequently happened that when they got near Mauch Chunk, a sudden rise would sweep them off, and they were lost.

"It became evident that the business on the Lehigh could not be extended as fast as the demand for coal increased, while it was necessary to build a new boat for each load of coal; besides the forests were now beginning to feel the waste of timber, (more than 400 acres a year being cut off,) and showed plainly enough that they would soon disappear, in consequence of the increased demand upon them.

"Under all these circumstances, it was concluded that the time had arrived for changing the navigation of the Lehigh into a slackwater navigation. The acting managers, who resided at Mauch Chunk, formed a plan for a steam-boat navigation with locks 180 feet long and 30 feet wide, which would accommodate a steam-boat carrying 150 tons of coal. These locks were of a peculiar construction, adapted to river navigation. The gates operated upon the same principle with the sluice gates in the dams for making artificial freshets, and were raised or let down by the application or removal of a hydrostatic pressure below them. The first mile below Mauch Chunk was arranged for this kind of navigation. *The locks proved to be perfectly effective, and could be filled or emptied, notwithstanding their magnitude, in three minutes, or about half the time of an ordinary lock.*"

One of the writer's objects, in making the above lengthy extract, was to enable the reader to trace the causes which led to the abandonment of the flash navigation on the Lehigh, and to see that it arose from no defect in the sluice gates or other works at first erected.

It must be evident to every one that the *Bear Trap Sluice Gates*, finding as they do their operating power in the hydrostatic pressure consequent upon the difference of level which they overcome, are capable of application to almost any width of opening; and that a gate of 100 feet or more in length could be manœuvred as readily as one of 24 feet, the only additional labour requisite being that of opening and closing a few more wickets.

In the descending navigation of the Lehigh, a case occurred where a fall of 16 feet in about 300 was overcome by one of the Bear Trap Sluices, though it was found necessary here to bolt a series of beams upon the platform, transversely across the opening, so as to moderate the velocity of the descending volume of water, by increasing its friction upon the bottom of the passage.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XXXV.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. I am not aware that Welby Pugin has been compared to Victor Hugo, but Victor may certainly be compared to Welby, for the one speaks in as depreciating a tone of the productions of modern architecture in France as the other does of those in England. Both are such outrageous admirers of the antique, that is, the Gothic style, that they have no admiration for anything else. In his "Notre Dame" the French writer has commented very freely, though somewhat *à la Smelfungus*, on several of the buildings of Paris, and, among others, on the Pantheon, which he designates a "Savoy cake"! In an article by him in the "*Revue de Deux Mondes*," he has since poured out his vituperation on the Hôtel of the Quai d'Orsay, the Ecole des Beaux Arts, the Chamber of Deputies, the Madeleine,—which it pleases him to describe as "a second edition" of the Bourse,—and the Chapelle Expiatoire, of which he says "rien au monde de plus bossu." "Oh, qui me délivrera," he exclaims, "des colonnades!" including under that term porticos also. It is, therefore, to be apprehended, that some of our own classical buildings—those of the Smirke school of design—would not find any favour in his eyes. After all, architectural criticism does not appear to be his forte, for he certainly can understand very little of the style he so energetically reprobates, when he insinuates that there is a strong resemblance of character between the Madeleine and the Bourse;—an opinion pretty much akin to that of the learned traveller who discovered a striking likeness between the temple at Baalbec and Covent Garden Church! There is, however, one expression of his that deserves to be noted, viz. "l'architecture seule, entre tous les arts, n'a plus d'avenir." In this, it is to be feared, there is some truth; and a rather disagreeable truth it is, since the very models that ought to stimulate us to rivalry are converted into obstacles in the way of originality and all effort of our own. Whatever be the style we happen to take up, we make no attempt at carrying it forward, moulding it according to present circumstances.

II. Among some other rather crotchety fancies in the article on "Gothic Architecture" in the last No. of the Quarterly Review, it is asserted that the Grecian style requires that caryatides should be made to express exertion and effort, as if oppressed by the weight of the entablature they support. Now, such figures ought, on the contrary, to manifest perfect repose of attitude, and tranquillity of countenance,—not any sort of effort to bear up against the burthen laid upon them—for that would indicate *weakness*, and their insufficiency for the office imposed upon them, but the ease derived from the more than ordinary power and strength adequate to their office. The mode recommended by the writer in the Quarterly would be at variance with every principle of æsthetics and architectural taste, and also opposed to the practice of the Greeks themselves, who made their caryatide figures to "stand at ease." Some over-sensitive critics protest against the employment of such figures at all, as suggesting painful ideas;—an over-strained refinement of feeling that ought to cause them to be very disagreeably affected by the sight of many other statues, put in situations which would be most perilous for any human being. They who are compassionately distressed at beholding female figures performing the duty of columns, ought to be filled with terror at seeing a statue stuck up on the top of a lofty column, or made to stand as sentry in a niche, exposed to every change of weather—frozen at one time, and fried in the sun at another. There is a good deal of the kind in art, which it is impossible to reconcile with common sense, supposing that mere common sense is to be the judge of it, and that the things which are so shown are intended to be mistaken for realities. How many extravagant absurdities are tolerated in painting! The

representations of Cherubim, for instance, are not only absurd, but disgusting; for a child's head cut off, and having a pair of wings tied to it, would be an object which, instead of affecting the heart, would be more likely to turn the stomach.

III. In the "Discours Preliminaire" to the first volume of his "Edifices de Rome Moderne," Letarouilly makes some sensible remarks, one of which is to the effect that those purely numerical relations and proportions, upon which so much stress has frequently been laid, have been greatly over-rated, since architectural beauty is not to be estimated arithmetically. It is, in fact, evident enough that mere mechanical beauty of proportions alone will go but a very little way in satisfying the eye, for those proportions may be observed *à la rigueur*, and the design itself may nevertheless be in abominably bad taste, or, at any rate, dull and insipid. The same writer also opposes the silly notion of the science of music being of any service to the architect. There exists only a certain vague analogy between the two arts; therefore, to fancy that any direct application of the rules of the one can be turned to account for the other, is no better than a chimerical whim, worthy of the philosophers of Laputa. If any such application be possible at all, it ought to hold good one way as well as the other; and the musician might certainly profit just as much by a knowledge of architecture, as the architect can possibly do by studying the laws of musical composition.

IV. In reporting the King of Prussia's visit to the British Museum, the newspapers have not informed us what opinion his Majesty expressed of the architecture of the building, on the plans and model of it being exhibited to him. Perhaps he thought it more advisable to keep his opinion to himself; and he might, moreover, be excused if he felt more astonishment than he expressed;—astonishment at the rigorous economy manifested in that national edifice, compared with the prodigality of the doings at Windsor Castle.

V. About two years ago the newspapers assured us that Prince Albert possessed more than ordinary taste for the fine arts, and that art might accordingly look forward not only to more hearty, but more intelligent patronage than it has hitherto been its fortune to obtain from a British court. Alas! for the sycophantic prophecies of newspapers! The so-boldly-predicted encouragement of art has as yet produced no other fruits than portraits of royal babies, and dog-kennels for royal puppies, except it be the huge royal christening cake—a most unequivocal specimen, no doubt, of superior *taste*. It may be that the predicted patronage is still to come—that we have mistaken the mere buddings and blossomings of it for the fruits. Such, it is to be hoped, is the case, but at all events, the blossoms themselves are of a very sickly kind. For aught that at present appears to the contrary, the future is likely to prove very much like the past, in a country where the sunshine of royal patronage to art has never amounted to more than mere *moonshine*.

VI. If we may believe Toussaint, mathematical science and theory are of comparatively little service in actual construction, and in fact are never trusted to, as architects themselves, he says, very well know, although they do not care to confess as much. "We are aware," he continues, "that such assertion will excite a hue and cry against us from the mathematicians, who will endeavour to prove, by A plus B , that it is *mathematically* false, and that we are altogether mistaken. Yet if we ask them how many architects they can reckon up in Paris who know anything of mathematics, we suspect they would be compelled to reply, in the verse of Boileau,

"Il y en a jusqu'à trois que je pourrais citer."

and even out of that number, how many are there who have recourse to their mathematics in constructing their buildings? On the other hand, we can oppose to their example that of Messrs. —, and —, and —. But we yield to the force of prejudice and opinion, otherwise we could here produce a rather long list of names of those who will deservedly stand high in the estimate of posterity as celebrated architects, although they are *absolutely ignorant of mathematics*! If for *Paris* we read *London*, the remark will, perhaps, hold equally good.

SUPPLEMENT AND ADDITIONS TO CHRONOLOGICAL TABLE OF ARCHITECTS WHO DIED IN THE 18TH AND 19TH CENTURIES.

BY W. H. LEEDS.

WHERE the precise date of an architect's death could not be ascertained, it is indicated by *ab.* (about). An asterisk * is prefixed to the names of those who have distinguished themselves, not as architects, but as writers on architecture, &c. The names of places in *Italics* denote that the architect was chiefly employed there.

DIED.	NAME.	BORN.	WORKS.
1742	Naumann, Joh. Chr.		<i>Dresden</i> , &c. Author of several publications.
1750	Pitrou, Robert	1684	Inspector of Bridges, &c. "Projets d'Arch. de Charpente," &c.
1753	Haerlemann, Baron	1700	<i>Stockholm</i> .
1753	Hartemann		<i>Sweden</i> .
1753	Neumann, Balt.	1687	Palace at Brucksal, Würzburg, and Werneck; Abbey at Schwarzach, &c.
1780	Morelli, P.	1730	<i>Rome</i> . Palazzo Braschi, Theatre at Imola, &c.
1784	Cooley, Thos.	1740	<i>Dublin</i> : Exchange, Four Courts, &c.
1785	*Gioffredo, Mario	1718	<i>Naples</i> . "Dell'Architettura," &c.
1785	Garcia, Josef	1760	<i>Valencia</i> , &c.
1786	Ivory, Thomas		Blue-coat Hospital, Dublin.
1789	Hiorne, Francis	1741	Sessions House, Warwick; Tetbury Church, &c.
1797	Duran, Ramon	1760	<i>Madrid</i> ; Pal. Torrepiñales, &c.
1799	Harsdoff, Caspar	1739	<i>Copenhagen</i> .
1801	Hiernöe, Jens	1748	Architect and Sculptor, <i>Copenhagen</i> .
1803	Palmstedt		Exchange, &c. <i>Stockholm</i> .
1804	Fantoni, Pio	1721	Engineering and Hydraulics.
1804	Desprez, Louis J.		Painter and Architect, <i>Sweden</i> .
1808	Piermarini, Giuseppe	1736	<i>Milan</i> . Pal. Reale; Belgiojoso, Mellerio, Villa Monza.
1810	Platzer, Jos.	1762	
1810	Cassels, Richard		<i>Dublin</i> , Waterford House, Kildare ditto, Lying-in Hospital, &c.
1812	*Patte, Pierre	1723	"De l'Archit. Theatrale"; "Etudes d'Archit." &c.
1812	Molinos, Jean		<i>Paris</i> . Theatre Feydeau, &c. with Legrand.
1814	Magens, Joh. B.	1748	<i>Copenhagen</i> .

CIVIL ARCHITECTURE.

Introductory Lecture on the state and study of Civil Architecture, delivered in the Theatre of the Royal Dublin Society, on the 5th and 8th of January, 1842.

By HENRY FULTON, M.D., Author of "Travelling Sketches in Europe and Asia,"—"Collegiate Architecture," &c.

"From the remains of the works of the ancients the modern arts were revived, and it is by their means that they must be restored a second time. However it may mortify our vanity, we must be forced to allow them our masters; and we may venture to prophecy, that when they shall cease to be studied, arts will no longer flourish, and we shall again relapse into barbarism."—SIR J. REYNOLDS.

THE study of civil architecture is a subject too much neglected. Civil engineering, painting, sculpture, and all the other branches of the arts and sciences receive public attention, while that of architecture is comparatively unaided and unknown. It is not to be expected that Arts' Unions will be established for the purpose of erecting temples and palaces; but I hope to be able to suggest a plan more feasible, and not less efficacious; for it is the privilege of few to erect edifices such as I have mentioned, but it does come within the reach of all to appreciate the beauties of such constructions.

I feel that, as an amateur, some apology is due to you for appearing in this place as a lecturer. The importance of the subject, and its not having been taken up by others better qualified, must excuse me; and I trust that any deficiency, arising from inexperience, may be balanced by the desire of furthering that object.

Should this effort be followed in this city by more scientific labourers, mine may in the interim obtain what astronomers call a heliacal rising, before any light I may be able to throw on the subject shall be lost in the superior attainments of those who may follow.

Feeling that I must leave to others to teach the art, I shall content myself if I succeed in creating in your minds that which so strongly exists in my own,—a desire to become better acquainted with its principles.

It is not difficult to prove that the ancients excelled the moderns in the fine arts of sculpture and painting. With respect to sculpture, witness the Apollo, the Venus de Medici, the Laocoon, and a host of others. As for painting, we have not any of the ancient master-pieces existing in our days; but we have the frescos found in the Baths of Titus, and other places in Rome, and a crowd from Pompeii and Herculaneum: and may we not argue, that as our best painters have not excelled, in drawing at least, the mere decorations of the ancients, how could modern works stand a comparison with those finished pictures, of which the frescos alluded to were probably copies executed by very inferior artists? It is well known that Raffaele himself took his designs for the Arabesques of the Vatican from those of the Baths of Titus.

The great number of frescos discovered in the places alluded to, forbids the supposition that their execution could have been expensive, such as we read (in Arbuthnot's Tables of Ancient Coins,) of their finished paintings—that a picture of Aristides was bought by King Attalus for 100 talents, *i. e.* about £19,000; that Julius Cæsar gave 80 talents, £15,500, for the Ajax and Medea; and that Apelles was paid nearly £39,000 of our money for his picture of Alexander.

Both painting and sculpture have, in the hands of such men as Buonarrotti, Raffaele, Canova, and Thorwalsden, made rapid progress to the high goal of perfection attained by the artists of Greece and Rome: but shattered and ruined as the works of Grecian architecture are, enough remains to eclipse the efforts of modern art, whenever a comparison can be made: that is, by comparing things of the same description with one another—the columnar ordinances of the Greeks with those of our own times—the originals with those professing to be derived from them.

We must admit that painting and sculpture have an advantage

which architecture has not, in the possession of models and objects of nature, from the study of which a correct taste can be formed; but it is more difficult to lay down fixed rules for the formation of taste, or say what should or should not enter into architectural composition: still we are not altogether left to steer without compass—for if we are to suppose that the first idea of architecture was taken from the erections of the feathered bipeds, then convenience and simplicity, so evident in their erections, should never be lost sight of in ours; and although we may add embellishments to the requisites just mentioned, such ornaments must harmonise with utility and simplicity of design, to constitute, as a whole—BEAUTY: and in all the works of creation, as far as we can understand them, we see that each part has a purpose for which just the requisite degree of strength is bestowed; and the painter or sculptor who would represent the club of Hercules wielded by a Ganymede, the burden of Atlas borne on the shoulders of Apollo, or the muscles of a Vulcan thrown into action to break a fly on the wheel, would be considered as devoid of taste. The same observations apply with force to the laws of proportion in architecture.

Let us now enquire why does not the revival of architecture advance in equal degree with the sister arts of painting and sculpture. It cannot be for lack of *pecuniary* patronage, for some of our architects make enormous fortunes. It cannot be for want of talent and information, for we have many who possess both: for instance, are we to suppose that the architect who delineated the ruins of Magna Græcia, was unable to produce a more correct building than the National Gallery at Charing-cross? No! The cause must be sought for in the ignorance and want of judgment of those who patronise them. Large sums are not given for bad statues or paintings, except by fools or dupes, because men of good taste know something of the value of both the one and the other. Not so in architecture; and the architect, feeling that it is in his power to pass on his ignorant employers any elevation which may look well in a drawing, has not a proper stimulus for exertion; and the science never will flourish, or architects be convinced of the necessity of a closer application to the principles of architecture in its purest era, until those who patronise them learn something of its rules and proportions.

I am not aware that it at all forms part of the acquirements taught at any public school, where so much is learned of the religion of the gods, but nothing whatever of the temples erected in honour of them; and which, as existing monuments, and affording useful models, we ought at least to be as well acquainted with as their worship, manners, or customs.*

Many are deterred from studying the theory of the art, from what they suppose to be the jargon of names which, it may be, convey no meaning to the mind. But let not this difficulty deter: when the thing is known, its name, if forgotten, can easily be found out, and it is not necessary for the amateur to enter minutely into all the details; without which labour, a respectable degree of information can be attained. And the eye which can appreciate the excellence of a statue or a picture, will soon learn to estimate the beauty of a well proportioned edifice; the taste and judgment will call for and be gratified by the reproduction of works of merit, instead of a multiplication of deformity, such as disgraces the national taste, and disfigures the capitals of our country.

In giving a brief sketch, it is not my intention to commence with the fabulous origin of architecture, or to dwell on that of the Etruscans and Egyptians, whose gigantic works, still existing, are objects more for admiration than imitation, more interesting to the antiquary than the architect. But I shall take the subject up when the art had attained its zenith in Greece, in the age of Pericles, when the three columnar orders of Doric, Ionic, and Corinthian existed in a state of perfection, which all subsequent alterations and modifications tended only to degrade and destroy. After the conquest of Greece, the Romans carried off many of the statues and paintings to Rome, which served them as models; but being unable to remove the temples, they

* I recollect showing a model to an architect's apprentice, of some two or three years' standing, who did not know a Doric from an Ionic column.

could at most carry home sketches, perhaps only mere descriptions of them, and like those of Vitruvius, erroneous ones; hence we have the Doric order with new proportions, and stripped of all ornament, and then called Tuscan, or left with some of them, and with the addition of other parts, and still called Doric. Hence also the shafts of the Ionic and Corinthian columns were attenuated, the capitals altered, and by the combination of the last-mentioned orders, a new one called Composite was formed. None of these alterations appear to be improvements, as we may see by a comparison of the Roman with the Grecian remains: the former indeed may strike the eye of an ignorant observer by its gaudy ornaments, but the latter recommends itself by its noble simplicity and well adjusted proportions.

All the buildings now existing in Italy, of a date prior to the subjugation of Greece, are destitute of columns (unless it be the temples at Paestum, the date of which is unknown, and which were the works of a Grecian colony settled there), nor indeed have we any remains of buildings of a date immediately subsequent to the conquest; but of those which do exist, the buildings of the earlier times, such as the Sybil at Tivoli, the Jupiter Tonans, and the Pantheon at Rome, are more to be admired than those of a later date, such as the Baths of Dioclesian, and the Vesta at Rome, the palace at Spalatro, as also the ruins of Palmyra and Balbec, in Syria, in exact proportion as they exhibit a departure from the Greek models, and to the length of time the practice of the art had passed into other hands.

It must be admitted, however, that the Romans, during this period, invented the arch, and its application—the dome. The Egyptians, from whom the Greeks learned architecture, covered their buildings with a flat roof, of a single stone; and as a roof for the choragic monument at Athens, commonly called the Lanthorn of Demosthenes, we find a single block of marble, nearly 12 feet in diameter, and hollowed out so as to resemble a dome.

The Greeks improved on this monolithic covering, and advanced one step further towards the discovery of the arch, as we see in the corbelled roof of the tomb of Agamemnon, at Mycenæ.*

But with the exception of the arch and the dome, the practice of architecture in Roman hands passed on from bad, in the age of Dioclesian, to worse in that of Constantine, when it appears to have lost all its pristine purity. And in the dark ages, when all the arts and sciences may be said to have been lost, architecture lay buried in its own ruins. The only attempt made to revive it in Italy, during this night of ignorance, was by placing the old columns of the Pagan temples in the churches, without reference to their proportions, as we see in the Church of Aracœli, on the Capitoline hill, and that of San Sebastian, outside the walls of Rome.

After this period there arose in Europe a new style, which is generally supposed to owe its origin to our intercourse with the East during the Crusades; a reference, however, to the ruins of Dioclesian's palace at Spalatro, will show the probable origin both of the Saracenic and the Gothic, the offspring of the same parent, the Roman modification of the Greek. And so far from the Gothic being derived from the Saracenic, both are modifications of the same style, taught by the same masters to the inhabitants of different countries, and each of these styles has as much resemblance to the Dioclesian, as this latter has to the Greek. It is true we do not see at Spalatro the clustered column and the pointed arch, but we have slender columns placed on consols, supporting circular arches, and distorted human faces are introduced as ornaments, just as we see them in the florid Gothic. As it was, until within these very few years, contrary to the creed and practice of the Mussulmans to make any representation of the human figure, this practice could not have originated with the Saracens.

Time will not permit our following up this part of the subject, however interesting it may be. We shall therefore leave the Gothic or Pointed style for some other occasion, and pursue that which is called Grecian.

It has been already stated that Grecian architecture, as well as

painting and sculpture, were neglected and unknown for centuries, although the world possessed the elements of all three. The works of the ancients were gems, the value of which was not appreciated by the possessors; for the rude figures carved by modern sculptors, before the middle of the 14th century, or the hard, wiry, stiff paintings before the age of Da Vinci, cannot be honoured with the names of sculpture and painting. The revival of both we owe to Italy. That country also lays claim to the resuscitation of Grecian architecture; and a number of her sons, at the head of whom stands Palladio, boast of complete success, although it does not appear that one of them ever saw a single specimen of Grecian architecture, and that their knowledge of it was only derived through the text of Vitruvius, and the Roman debasements, which presented to them beauties they did not profit by—taking only the worst parts of this deteriorated style, which however formed the only beauties of their own compositions.

The estimation in which Vitruvius and Palladio are held in our own country at this day, may be judged of when we hear, *ex cathedra*, "that the highest in rank in Italy are not ashamed to be professors of an art which Palladio adorned and Vitruvius taught." To the architects who hold such sentiments I would say—Gentlemen, until you get rid of all such opinions, pure architecture will not flourish, or your profession be placed on that pinnacle of public estimation to which by *birthright* it is entitled.

About the middle of the 16th century, Palladio flourished. Many other architects of equal merit (if indeed he had any), lived before him; but it would be useless to detain you with a mere catalogue of names. Palladio stands confessed as the author of a style, and the founder of a school, still much admired in this country. He has left us drawings of most of the Roman buildings which were in existence in his day, and of course more perfect than they are at present. So far we are his debtors; but strange to say, that although he must have spent much time in measuring the ruins, and designing their restorations, not one of his own designs, except the internal arrangements of a little theatre at Vicenza, appears to harmonise with, or bear any resemblance to the buildings of the ancients.

The chief defects of this school are—

Columns raised on stilts.

Columns placed one above the other.

Columns of different orders ranged in the same elevation.

The two frequent use of engaged columns.

Columns swelling in the middle (offensive to the eye, because an indication of weakness).

Thin columns having wide and irregular interspaces.

Tapering pilasters.

Finishing the tops of doors and windows like the cables of houses, or the roofs of camp bedsteads.

Swelled friezes. And lastly,

All simplicity destroyed by broken lines and partial projections.

I offer no excuse for dwelling on this catalogue of vices, because they have been copied, and are copied every day, in too many instances in our own city. We shall therefore proceed to particularise and notice these errors in detail—that when you see them in your daily peregrinations, you may know them; and when public taste and judgment are better informed on the subject, we may hope they will not continue to be perpetrated.

In speaking without reserve of the modern buildings of this city, I am aware that a door is opened for criticism on the opinions advanced. Well: let it come! However the controversy may terminate, it must lead to the elucidation of a favourite subject. I freely admit that they who have designed those buildings have what is esteemed high authority for what they have done; and if they have not done better, it is because public taste (ill informed as it is) sought for no improvement.

I feel that it would be unworthy both of you and myself, were I to stoop to conquer by flattery the displeasure of any, in setting before you all a stimulus for exertion in the acquirement of architectural knowledge.

Most of the errors I have mentioned may be found in the Palace of

* I here beg to correct an error made in the Travelling Sketches, vol. ii. p. 209, where the choragic monument is mentioned, instead of the tomb of Agamemnon.

Dioclesian at Spalatro. That emperor, like our own George IV., was a patron of the arts, and immense sums were lavished both at Rome and Spalatro, at London and Brighton; but architecture is not much indebted to the florid taste of either.

The innovations of Dioclesian's time are so striking as to merit his name being given to the style; and as the term Gothic was applied by Sir C. Wren and others to the pointed style, may we not call the Palladian modification of the Dioclesian by the name of Vandal.

The term Gothic, as a name of contempt, is now felt not to be deserved by the beautiful pointed style, which although charged with meretricious ornament without limit, regardless of all order, trifling and weak in detail, is yet magnificent and beautiful in the aggregate.

The Vandal is chargeable with all the defects, which are not redeemed by any of the beauties of the Gothic. But to proceed with the list.

Columns on stilts.—These may be seen at Spalatro, though not in the same perfection as on the front of Trinity College, or the continuous stilt or too lofty stylobate of the College of Surgeons in Stephen's-green. We also find it in the portico of a temple in Umbria, which Palladio says was the only instance of the kind he had seen. He seems, however, to have been enamoured with the invention, for it enters largely into many of its structures. At best it is a shabby expedient to save the expense of larger columns, which would be required to give the height of these smaller ones and their stilts. I ask, what is the use of columns in any case, unless it be for effect? And if that be the object, is it not defeated by placing them above the range of vision? Wherever the columnar ordinance is used, columns must be principals; and is it proper to place principals above the range of the eye.

Columns placed one above the other.—We have no very striking example of this in Dublin; but we find it in the west front of St. Paul's and many other buildings in London; and Palladio says the Tuscan should be placed underneath, then the Doric, then the Ionic, then the Corinthian, and lastly, the Composite order—rules fit for the erection of a tower of Babel. It must be granted that columns should harmonize in apparent solidity with the weight of the superincumbent cornice which they are to support. This effect will be destroyed, if one or two other rows of columns and accessories are to be placed above. The Greeks used the expedient to a certain extent, as in the example before you; but only as a choice of evils—for if the internal columns of the cella had been large enough to reach the inclined roof, they would not have harmonized with the other columns which they were to be viewed in connection with; besides, they are of the same order, and were placed almost out of view.

Columns of different orders ranged in the same elevation.—A design never can be chaste, if it contain more than one order; and in this respect, the west front of the Bank of Ireland, the old Parliament House, is disfigured by the Ionic semi-columns in juxtaposition with the Roman Corinthian portico. The Bank is like a man wearing a coat with one sleeve of a different colour, both from the other and the body of the garment—a fashion not yet adopted in dress. This Corinthian portico wants the elevation of a basement, and by giving it that, it would be made to overtop the body of the edifice. I understand that originally it had a basement, before the street was filled up to its present level. In short, this deficiency is to be objected to almost as much as the other extreme of having a too lofty stylobate; and so sensible was the architect who erected it, of the injury it sustained in being shorn of its fair proportions, that he never could bear to pass through Westmoreland-street, after the operations of the Commissioners of Paving.

Did time and place permit, the history of this portico would be as instructive as the account given by an Irish historian, called Swift, or some such name, of the violent contest between two powerful nations, as to which end of the egg should be broken. Suffice it to say, that our domestic struggle for prerogative coeval with that for the Bill of Rights, terminated by the belligerents, the Lords and Commons, selecting different orders of architecture for their respective entrances to the same edifice—thus agreeing to differ, and furnishing most con-

vincing arguments, which may be used (according to an ordinary formula of our profession,) *pro re nata*, for or against a repeal of the legislative union.

It has been said that the Greeks, particularly with the Doric order, placed columns without any base. They did no such thing; you will see, in the example before you, that the steps form an ample basement. What would the finest statue that ever was made appear to be, with its feet sunk in the ground or cut off? The eye of criticism, and we are all critics in our way, dwells rather on defects than beauties; and one blemish more than counterbalances twenty excellencies.

Engaged columns.—The too frequent use of this expedient is to be condemned. The effect of columns in a composition arises not only from their graceful forms and well adjusted proportions, but from the lights and shadows which play around them—the chiaro-oscuro of architectural composition; and this effect cannot be obtained by engaged columns. Instances of this may be seen in the front of Trinity College, and the College of Surgeons in Stephen's-green. In the example before you, (the Maison Carrée) may be compared the engaged and disengaged columns. We are not, however, to take the engaged columns of the Bank of Ireland as the design of its architect, for they originally formed an open piazza; but for some wise reason, or perhaps for no reason, they were subsequently built up as we find them at present.

But if we must have attached or engaged columns, I would suggest that they should not be diminished at all, but carry the same diameter from base to top. I never heard of any example of this—but on looking at any of the Palladian Arches, as for instance, those in the principal front of the Bank of Ireland, you will find that the back ground (if I may so speak) to which the columns are affixed, appears like an inverted pyramid, a figure which cannot have a pleasing effect. This is not the case when the columns are detached, on account of the depth of the shadow.

Interspaces of columns.—In the Doric order, the rule is clear and well defined—one triglyph over the centre of each column, and another over the centre of each interspace. The spaces between these triglyphs, called metopes, must be a square, the length of whose sides is regulated by the diameter of the column at its base. These triglyphs are supposed to represent the ends of the beams intended to form the ceiling, and if too many of them be introduced, the architrave on which they rest would be too weak, or what is the same thing, appear to be too weak, to support the weight. I admit that there is an additional triglyph introduced in the propylea on the Acropolis; but it ought to be considered as forming the exception—not the rule; and appears to have been for the purpose of leaving a wider space for the entrance of processions. Another instance occurs in the Doric Portico of Augustus, but it is of Roman construction. This innovation has been extended by Palladio and his modern followers; and we find, in some instances, six or more introduced, and in situations where they are not at all requisite; for instance, on the cornices of windows or door-ways. Why should beams be placed there, or in the inside of buildings, as we see in the chapel in Marlborough-street? I am not aware of any ancient example of this. The east portico of the chapel just alluded to shows a great poverty of conception in the architect, who has placed an additional triglyph between each column—indicating either that the columns are too thin, the interspaces too wide, or the frieze too low. At least a hundred instances of this bad taste occur in the public and private edifices of this city, and scarcely an example of the contrary. But compare the portico in Marlborough Street, notwithstanding its defects, with the Vandal Doric one in the College Park, the design, I believe, of Sir William Chambers, and you will perceive its superiority.

Tapering pilasters.—This extraordinary practice is of the Vandal school. As the situation of these square columns or pilasters is at the angles of the building, they cannot of course square with the wall unless it were made pyramidal also—the absurdity of which is obvious.

You will find this in every building in Dublin where they are used, except those of a late date—a departure from the Vandal school to

be bailed with satisfaction. The Greeks never tapered their square columns or pilasters; nor did the Romans, in some of their best erections, as for instance, the portico of the Pantheon. I beg to call the attention of the profession to this, as I have heard a contrary opinion expressed in this country. You will find the pilasters of the portico in Upper Gardiner Street partially tapered; which is surprising, as a Greek model appears to have been taken for the Ionic capitals of its columns. In the same example may be seen the poverty of a four columned portico, as the tympanum of such a structure must necessarily appear heavy, and have too high and abrupt a pitch. Still it is in better taste than the unfinished and much admired Vandal portico of St. Thomas's church. It has been considered by many, that the circumstance of this latter portico being allowed to remain unfinished is discreditable to the parish; but the reverse of this conclusion is nearer the truth, as far as architectural taste is concerned.

Gable-topped windows and doors.—Of all the strange devices of which I have given a list, this is the most strange. The earliest example of this practice with which I am acquainted, is to be found in the Pantheon at Rome, the most recent in our own city; of late it has been discontinued in London, but still finds admirers in Dublin. I do not know whether we are indebted to an architect for this, but I presume not. And here I may allude to the practice of taking builders out of their proper sphere, and allowing them to supersede the architect. This is as foolish as it would be (could we suppose it possible,) that one whose personal tabernacle required repair, should have recourse to the manipulator of medicines, instead of the well informed professor of the healing art. But I must add, if the art is to be taught from the dogmas of Vitruvius, and adorned from the designs of Palladio, it matters not to us on whose shoulders the mantle of patronage may fall, on that of A. or B., the architect or builder. After all, it may be my misfortune not to be able to appreciate the beauty of the building in question; no doubt posterity will do it justice, for it will come under their notice as the property of the President of the Royal Institute of the Architects of Ireland.

The profession of architecture in this country is placed in a false position—pressed on the one hand by that of aspirant builders, and neglected on the other by a *discerning public*, which is not only unable to decide on their respective merits, but is also ignorant of those principles on which alone good taste is founded. Under these circumstances, it is not surprising that every edifice assuming an architectural form, is praised or reviled according to the number and influence of the friends of the architect. Committees and individuals requiring architectural plans, decide on the relative merits of designs submitted for their inspection, more from the beauty of the drawing, than any reference to the effect likely to be produced in stone and mortar: hence he who is the best draughtsman will be the most fortunate competitor; and the work may be executed without producing credit to himself, or satisfaction to his employers. This state of things could not exist, if public taste were better informed.

The Pantheon was first used as a church by Pope Boniface IV., at the commencement of the 7th century; but the state of the arts in those days forbids us to suppose the altars had not been erected before that period; they are supposed to have been added by Septimius Severus. Almost all the Vandal school have left specimens of this innovation. Palladio, M. Angelo, Inigo Jones, Sir C. Wren, Sir Wm. Chambers, and many others of our own times, who seem to follow, for no better reason than because others have led the way. Some of these architects, conceiving, I presume, that variety is pleasing, give us a gable-topped and an elliptic bed-topped window alternately.

When I see a well proportioned window or door thus disfigured, I am forcibly reminded of the story of the worthy country squire, who hired a strolling artist to paint wigs on the heads of Vandyke's portraits of his ancestors. I was unable to discover the use of these window tops until I saw, on the front of one of Palladio's palaces in Italy, two undraped colossal figures, reclining in a perilous posture above each window, literally in a *tête-à-tête* position, like slack-rope dancers resting themselves. Would it not be in better taste to con-

sider these window-tops as hobby-horses, and place a saddle and a rider on the summit of each, in a more secure position.

Swelled Friezes.—This invention bears a close resemblance to an article of dress said to have been used by our great grandmothers, called a *bustle*; and if it be true that these ancient dames wore any such ornament, no doubt the hint was taken from them.

I cannot discover that the ladies of old ever placed the bustle on the front elevation, as we see it in the Bank of Ireland; nor can I from memory say whether the old lady in Threadneedle-street has it or not. If the frieze were constructed of any plastic material, such as wet clay, this is exactly the form it would take on being subject to pressure from above; therefore it indicates weakness. As bustles have long since gone out of fashion, we may hope the swelled frieze will follow. On examining the Bank of Ireland, you will find it discontinued on the east, and afterwards on the west front, for which the architect of that portion of the building deserves great credit.

The last subject of the list is—

Broken lines and partial projections.—A knowledge of painting and sculpture is among the many requisites laid down by Vitruvius, as necessary to constitute an accomplished architect. But architecture has suffered in the hands of the professors of the sister arts; and M. Angelo, Buonarrotti, and Raffaele have tarnished their bright fame by their architectural productions. Inigo Jones left England as a painter, and returned as an architect.

The finest field that ever was opened for the genius of man, presented itself to M. Angelo. He enjoyed the patronage of Leo X., a prince born of a race of patrons of the arts. Rome presented to him a vast quarry of marble, ready chiselled; he was required to erect on the Capitoline a building for a senate-house and museum, near the site of the Temple of Jupiter, which once crowned the mount "the pride of Rome, the admiration of the world." Before him lay the ruins of the Forum Romanum, and on his left that of Trajan; to the right and behind he had ruins of temples, triumphal arches, and columns in abundance: he began by turning his back on the Roman Forum and all the beauties of art which it presented to him, and constructed three sides of a square, mean, trifling, and frivolous in design, presenting specimens of nearly all the monstrosities of the Vandal style. He has adorned Rome after the manner of Palladio, his cotemporary; but his works stand no comparison with the still existing monuments of past glory: and the descendants (if such there be) of the Scipios, the Ciceros, and of him who was "the noblest Roman of them all," although the possession of St. Peter's may flatter their vanity, yet sigh as they pass on—*ma Roma, Roma, non e piu com era prima.*

It must be admitted that M. Angelo's lofty dome on St. Peter's, and the cornice on the Faranese Palace, redeem his name from indiscriminate censure. It was part of his plan to make St. Peter's a Greek instead of a Latin cross, and to give it a portico like the Pantheon. As it is, the exterior of the dome cannot be seen from ordinary situations; and in taking the design before you, the painter must have been on the top of one of the houses between the church and the Tiber.

Canova, too, the bright star of modern sculpture, into whose works the spirit of the Apollo, the Venus, the Laocoon is instilled, has left us a design for a church, sufficient to show that he studied not the architecture as he did the sculpture of ancient Greece.

In fact, painters cannot well be good architects, as far as the Greek style is concerned. Accustomed to feel that "there is no beauty in straight lines," they break up the building for the purpose of giving pictorial effect to the design, and "however contradictory it may be in geometry, it is true in taste, that many little things will not make a great one." An architectural drawing of a Greek subject is a stiff, formal production, totally different from Hogarth's line of beauty. Models are the fittest representations for the public to judge from. Take this temple and break up all its cornices; place its columns in any line but a straight one, and the painter will prefer it for a subject; but if in that state it be raised in stone, its beauty will be lost, because its simplicity will be destroyed. According to Burke, simplicity is a source of beauty—it is essential to that of Grecian architecture.

The Parthenon, and the temple of Neptune at Posstum, are now stripped of ornament, yet they make up by simplicity and unity of design, for the want of it, except in the estimation of those architects who conceive that they are defective in not having steeples!

We may not be going too far in saying, that the Parthenon is the best, and the temples at Posstum the earliest examples of the Doric order. The former was erected nearly 500 years before our era, in the best days of Grecian art. Of the date of the latter we know nothing, except that a colony from Greece settled in Calabria, and founded the city of Posidonia, before Rome was built: even if we did not know this, they bear the impress of Grecian mind, and reject the hand of any other master.

It is the practice of modern times to take a Greek or a Roman portico, and place it in front of a windowed, corniced, and balustraded building like our Post Office (Dublin). By this expedient, unity of design is destroyed; and however correct or beautiful the portico may be in itself, it will not appear to the same advantage as if its cornice squared with the sides of the building. When this arrangement may be incompatible with the required purpose, it is much better to dispense with the columnar ordinance altogether, and have recourse to some of the other styles. I am rejoiced to find that a new system has lately been introduced into England, of erecting plain, symmetrical structures, surmounted with a handsome unbroken cornice, such as that of the Faranese Palace at Rome. In some remarks which I published on architecture, I pointed out the advantages of this style, before I was aware that its introduction was in contemplation.* The nearest approach we have to this style in Dublin is the Royal Hibernian Academy. The unbroken line of the cornice at the top of the building has a good effect. It will stand a comparison with the Palladian one on the newly fronted edifice in Merrion-square; and the recessed portico is much better than one placed up against the main structure would have been. There are however some great defects in this building: the Vandal headed windows, resting on little bustles; the Doric columns of the portico are too slender, being about seven diameters high, which is two more than they ought to have been under such a superstructure. The angles of the walls, next the columns, should have had pilasters or antis. The balustrade at the top of the building is in bad taste. Balusters are deformed dwarfish columns of the Vandal, and are not in good keeping with columns of the Greek school, no more than a pigmy would be a suitable quiver-bearer for the Pythian Apollo: besides, a cornice is the proper finish for an architectural structure. The arrangement of the windows also is bad, not corresponding at all with the opening of the recessed portico.

One cannot view our Custom House (Dublin) without feeling that all simplicity was sacrificed in its construction, according to the false taste of that period. If the cornice had not been so much broken up, and there had been no balustrade or attic above it, the effect would have been good: as it is, the building can only strike us for its magnitude, the good quality of the stone, and the fine situation it enjoys. It must be admitted that when viewed from such a distance that its faulty details cannot be observed, the effect is fine, and just such as it would have been from every point of view, had Greek simplicity guided the architect in its design.

What is it that rivets the eye on the Irish Round Towers? It is not any historical association, for the history of our country does not speak of them: neither are they Vitruvian nor Palladian; they are better—simple, graceful, and beautiful; and therein lies their attraction. May I be permitted to speak on behalf of that of Glendalough, which, for want of a little restoration, bids fair to be in ruins ere it be recorded in the long expected work on Round Towers, from the pen and pencil of Mr. Petrie. Surely his Grace the Archbishop of Dublin, who is lord of the soil, cannot be aware of its delapidation.

The same observations apply to the Egyptian obelisk, commonly called Cleopatra's Needle, of which there are so many in modern Rome. The best imitation of this, with which I am acquainted, is to be found in the Primate's demesne at Armagh; and although it is not

to be compared in magnitude to the Wellington Testimonial in the Phoenix Park, and did not perhaps cost one tenth of the sum paid for the erection of that trophy, yet far excels in beauty of proportion; showing us that mere masses of material, unless arranged with taste, fail to produce satisfaction, whatever name may be given for the purpose of rendering them imposing.

The combination of parts of different orders in the same building is to be avoided, for although the association of Goths and Vandals, as the destroyers of the remains of ancient art in the south of Europe, be strong in our minds, yet the union of the Gothic and Vandal styles cannot be recommended. A striking example of this occurs in the Duomo at Milan; it has Vandal windows and doors, although all the other parts of the edifice are florid Gothic.

The Greeks never surcharged their buildings with ornaments; yet both they, and after them the Romans, devoted the greatest care to the composition and finish of works never intended to come in close contact with the sight. I have been perfectly astonished at the beauty of the mouldings and capitals, when strewn on the ground amidst rubbish and ruins. Together with a deviation from the Greek models, a desire for multiplicity of ornament and novelty was introduced; and long ere the fall of the Roman empire, luxury and refinement, which sapped their power in the government of the world, tended also to the decline of architecture. May we not express a hope that a recurrence of the same principles may not produce the same effect in our own times and country.

The Elgin marbles in the British Museum, which challenge a comparison with the best works of antiquity in the possession of other countries, were, for the most part, placed on the tympanum of the Parthenon, upwards of 50 feet above the level of the eye. The column of Trajan is 132 feet high. These casts were taken for me by a man who was suspended from the top in a basket; you may judge of the finish of the marble by the casts, after the original had been exposed to the weather during so many centuries.

I have now endeavoured to set before you some of the prevailing errors of modern architecture, and some of the beauties of the ancient. In advocating a closer acquaintance with the latter, I may quote the words of an eminent painter, who observes, "From the remains of the works of the ancients the modern arts were revived, and it is by their means that they must be restored a second time. However it may mortify our vanity, we must be forced to allow them our masters; and we may venture to prophesy, that when they shall cease to be studied, arts will no longer flourish, and we shall again relapse into barbarism."

ON ARCHITECTURAL PRECEDENT.

SIR—Permit me, through the medium of your journal, to make a few observations on your correspondent H. S.'s remarks on "Architectural Precedent," which appeared in your journal for January last. I think it is but right, before we condemn *in toto* the use of precedent, to inquire a little into its origin.

Precedent I conceive to be coeval with architecture, and that of architecture with the necessary wants of man; and as age after age became more refined, so the wants, and necessarily the architecture. It would be impossible to find a nation throughout the world, at any period of its existence, whose architecture did not progress in an equal ratio with its refinement, but throughout never changed its character. The first laws being laid down, the architects invariably followed them: and why? because they were made to suit the wants of the nation, both as regards climate and economy. Indeed to such an extent has this been carried, that were it not for the remains of architectural elegance scattered up and down that part of the once refined world, what would there now remain to tell of the highly polished Athens, or of the internal comfort and domestic economy of the ancient inhabitants of Pompeii and Herculaneum? Your correspondent, in his desire to do away with precedent, starts out with condemning the course of study pursued in an architect's office. Now I should rather say, the fault (if it be one,) does not commence here, but in the very first dawn of the pupil's infant mind, because it is the most natural course of events, and necessarily so, that seeing one kind of architecture, the mind gets imbued and impressed with a

* Travelling Sketches in Various Countries, vol. ii, p. 206.

love, and I might almost say with a veneration for it. To produce an entire change in architecture, which appears to be the wish and aim of your correspondent, it would be necessary that the inventor, if I may be allowed the term, should be brought up in utter ignorance of our present style, and almost destitute of any knowledge of our domestic economy; and then it cannot be expected that he should bring the same to perfection, as it is the natural course of Providence that all things shall progress, "necessity" being made the "first law of nature."

Precedent, I think, must appear to every person to be necessary to the right discharge of almost every duty of our lives. It must actuate all; and indeed so mixed up is it in every grade of society, that it does actuate all our movements. It has done so from Adam's fall, and must continue to do so to the end of time.

Your correspondent next repudiates the idea of adhering to one period of architecture in forming a design, and inquires, why should not an ornament of a late period be introduced in a design of a much earlier, provided the same looks well? And forsooth, why not? why not unite the chiroli mould of the Norman to the compressed arch of the Tudor, and the mongrel column of the late degenerate Elizabethan school? Perhaps your correspondent would affirm that this would not look well; and truly it would not to a correct eye, but to a pupil brought up according to your correspondent's wishes, such a *conglomeration* would not appear incongruous, neither would he understand why it should not be so. Should such a state of architecture ever arrive, when an architect could with impunity amalgamate different periods, and I might add different styles, for the evil when once let in would not stop,—should such a time ever arrive, architecture will then be on the wane, England's glory will be setting; for, to go back to precedent, there has never been a country whose architecture has degenerated, but whose whole energies have been crippled, and whose glory has set. While at the same time I would give to precedent its place, I would not be unmindful of the great use of it. I conceive it to be the curb of the architect's imagination; not that he is servilely to follow all its dictates, but to guide his judgment, and having studied fully all its bearings in ancient architecture, he will be better able to come to a correct notion of what true architecture ought to combine, and will act rightly, having had his mind thus well schooled. This I conceive to be the great use of precedent, not only in architecture, but in every other study.

Having thus inquired into the great use of precedent, allow me now to inquire into the right use of it. To make a right use of precedent, it requires a thorough knowledge of ancient architecture, and not of architecture only, but also the domestic habits and economy of former ages. To do this, it is impossible that any man can gain it by the "road side,"—it unfortunately is not written so clear, that he that runneth may read. What then is required? much more than, I am sorry to say, the Royal Institute of Architects imagines, or I cannot believe that men in the highest ranks and ability in the profession would ever remain so supine to the best interests of their profession. Why is it that that body does not bestir itself, for now is the time, while they have such interest, their President being the representative of royalty in the sister land? Why not obtain for architecture what the Royal College of Physicians and Surgeons have done for medicine? Then, and not till then, will architecture and architects take their proper stand throughout the country. What can militate against architecture so much as the fact which is a very common occurrence in the country, of a common joiner, with a little more *naïveté* than his brethren, practising as an architect, to the great detriment of the legitimate architect? And that man gets supported: why? because he undertakes work at a much lower charge than the other; and merchants, who only look at the pounds, shillings, and pence, are well satisfied, although there is the greatest incongruity, such as I have seen. Amongst numberless others, to mention a small thing, of putting the Tudor rose in the fascia of a Grecian shop façade, and otherwise mutilating the style. Of course this, to your correspondent, would not be any detriment or eye-sore, as it looks well to a man who knows no better.

I am, Sir,

Your obedient servant,
J. M.

Sheffield,
Jan. 26, 1842.

ARCHITECTURAL PRECEDENT.

I WAS agreeably surprised upon finding two correspondents expressing ideas so nearly coincident with my own on this subject, when I had rather

expected that, if any notice was taken of the matter, it would emanate from the adverse party, and convey anything rather than approval. It would be well for architecture, if a larger proportion of its professors held the same liberal views as those espoused by "Ditto" and "J. L."

The remarks of the former so entirely agree with my own notions on the subject, that they do not call for any reply: J. L., however, in consequence of the want of explanation, has not taken that view of the influence of classical education which I had intended to convey. Its general effect upon the public mind—the bias which it produces in the feelings of society—the erroneous impressions it gives rise to—were the results to which it was wished to draw attention.

It will, I think, be at once conceded, that if one subject be allowed to engross any mind, to the exclusion of all others, that subject will be almost certainly magnified in importance far beyond its proper standard, even though that mind may be well informed in other departments. How much more, then, will this be the case, when the attention has been confined to one study during the whole course of education, when all other kinds of information have been withheld, and when there has been no opportunity of drawing any comparison between the merits of different branches of knowledge, or different races of men? Is it not probable, therefore, that when a young man has spent all the early years of his life in close attention to one study—the history of the ancients, their wars and enterprises, their heroes and their victories, their cities and temples, their orators and statesmen—when he looks on their philosophy as the highest attainment of human wisdom—when he reads of their deeds in the high-flown poetry of Homer and Virgil—when, in the warmth of a youthful imagination, he paints their actions, if possible, in brighter colours than even the poets themselves have done, and takes his imaginations for realities—when he becomes infected with the admiration for martial glory, and thinks nothing so noble as war—when he attaches to virtue the meaning given to it by the Romans, and looks upon animal courage as one of the highest attributes of human nature—when, I say, he does all this, and at the same time knows little or nothing of the grandeur of modern science—when he has not the faintest conception of the gigantic mass of knowledge collected by the philosophers of the present day—valuable knowledge, ennobling knowledge, knowledge which enlarges the mind, and advances mankind physically and mentally—when he knows nothing of what is *done*, as well as what is *known*—nothing of the wonderful achievements of modern ingenuity, nothing of the almost miraculous results of the applications of science to the arts and manufactures—under all these circumstances I ask, is it not probable—nay, is it not certain—that he will get up from his studies with a prepossession in favour of the ancients?—a prepossession which will tinge all the opinions of his after life—which will lead him to admire all that is old, in virtue of its antiquity—which will lead him to make wrong estimates of the beautiful and the noble—a bias, in short, which will be an injury to himself and to society.

This is a very interesting subject, one on which much more might be said, were it not irrelevant to the character of this publication; and as it is, these remarks are only admissible in virtue of their relation to architectural precedent. Under these impressions it is that I come to the conclusion, that the prejudices of society in favour of what is ancient are to be mainly ascribed to classical education, and that the readiness with which architects accede to the dogma of the unsurpassability of ancient architecture is probably attributable to the same cause.

I quite agree with the opinion, that the study of existing specimens of architecture is necessary for the cultivation of taste, and that taste requires education as much as any other faculty, and I never for a moment intended to imply any general disrespect for the works of antiquity: on the contrary, I admire many examples, both classic and Gothic, perhaps as much as any one. But there is a great difference between admiring an object because it is really beautiful, and admiring it because it is old, or because it is the work of a certain people. There is a great difference between praising what is worthy of praise, reserving to one's-self the right of censuring what does not please, and subscribing to a wholesale approval of everything. There is a great difference between studying examples handed down to us with a view to the cultivation of taste, and studying with the intention of copying.

H. S.

Derby, Feb. 16.

P.S. In the original paper, page 23, second column, and the third line from the bottom, for "spurn" read "spread."

FRESCO PAINTING.

A Paper by JOHN WHITE, Fellow, relative to two Tablets of Slate covered with Pozzolano and Stucco, and painted in Water Colours, read at a Meeting of the Royal Institute of British Architects, January 31, 1842.

As the public attention is at present directed towards ornamental wall painting, particularly to the mode called *Fresco*, I have thought that it may be interesting to the Royal Institute to inspect two preparations made in the year 1824, on which have been painted in water colours subjects calculated to demonstrate that there exists a capability of painting on a permanent base, and with equally permanent colours.

The mode which has been adopted, was to cover two tables of slate with a coarse clay Pozzolano of British manufacture, and upon the surface to trowel with a glass float a thin stucco, composed of finely-ground lime and fine flint Pozzolano, mixed with weak alum water.

The paintings were executed before the stucco was thoroughly dry, and on them was added a thin solution of white wax in spirit of wine: this was done in order to insure the colours from being washed off when the paintings required to be cleansed, which has recently been done.

Seventeen years have elapsed, and the paintings are in the same condition as when first done; and I believe they will endure for any period of time. The tablets were prepared by Mr. Henry Crace, who painted that which is of an oblong form; the upright one was painted by a student of the Royal Academy, since dead, of the name of Robinson.

The advances recently made on the Continent in the decoration of buildings, by the introduction, or rather the restoration, of fresco or wall painting, has led me to observe that historical painting is capable of being executed in this country, and of being employed as an embellishment of our public edifices on a suitable basis, and to congratulate the Institute on the sentiment which is rapidly progressing, that the artists of England ought to be patronized in the enlargement of their ideas, by offering them the walls of our newly-constructing buildings as fields for their exertions on an expanded scale.

That this sentiment may not be checked, it is hoped that the Royal Institute will, by its expressed approbation, assist in forwarding every effort which it shall deem worthy its attention, and that the sense of the country generally will exhibit itself in favour of such patriotic labours as those which the late James Barry has displayed on the walls of the great room of the Society of Arts in the Adelphi, unfortunately, alas! too little imitated or patronized since their execution, now much more than half a century ago.

One difficulty in water painting on stucco has always presented itself, namely, that arising from the caustic quality of the lime used destroying most colours of a metallic or vegetable composition, leaving few more than the earths as proper articles to be employed by the painter on fresh walls; and when the walls are become dry, then the water colours adhere ill, and never are brilliant.

To remedy the evil, it will appear, on the inspection of the tablets now presented, that the surfaces they exhibit are not only sufficiently smooth to admit of vast facility or rapidity of execution, but that, inasmuch as the quantity of lime used in their preparation is small, it has not materially taken away the power or brilliancy of the work. In the upright tablet, which represents a copy of a fragment of a cartoon by Julio Romano, in the possession of Wm. Lambert, Esq. of the Woodhouse, Finchley, Cologne earth and a little blue has been used, diluted with water, in which a little shell lac was dissolved, by pounding it with borax, this solution making the colour pass very freely with the painting brush, and only tinting the mixture by the rose colour arising from the lac—in my opinion not at all objectionable. In the year 1825, this picture was shown at the Society of Arts, where it was washed, and rather rudely rubbed by some persons in their investigations as to its permanence. It has never been touched since that period, excepting that within a few days it has been rubbed with a flannel, to remove the dirt and smoke on the surface. The oblong tablet was painted, not in my presence, by Mr. Henry Crace. I am not acquainted with what solution he used with his colour, other than that it was water; but it is not permanent against washing.* Respecting it, it is to be observed that the artist, in proceeding from the left to the right, has evidently improved, and that there is great delicacy in the shading of the figure on the right, more indeed than I have remarked on any other surface, excepting enamel.

There is a little splendour on the face of both pictures, but it does not

* I fear it was white of egg, too much used by ancient painters on walls and stone.

amount to the glare of oil paintings. I persuade myself that at almost any distance from paintings executed in this mode, what they intend to represent will be conspicuous, whether observed far or near, with almost equal advantage to the spectator, which is not the case with oil painting.

I have noticed in my letter, that the stucco which has been applied on the face of these tablets has been composed with very fine ground lime and calcined flint reduced to a powder, mixed with a little alum water, and trowelled on with a glass instrument. These materials have been smoothed down till the surface was sufficiently perfect, but yet not so triturated as to destroy the setting quality of the lime: great care is to be observed in this particular, and the skill of the workman is to be called into action. I need hardly notice, that it is the combination of the mechanical disposition of the fracture of the pozzolano flint and its burnt nature, which produce the strong adhesion and strength of the whole plaster, as most architects now admit this to be the fact. It was well known and understood by the Romans, who so extensively used the natural as well as the artificial burned earths.

This latter observation leads me to the importance of reflecting on the necessity of constructing buildings with materials which are incompatible, either by working them, as it were, stone and stone, or brick and brick, so united by workmanship as that there should be no shrinking, either in the foundation or superstructure; and that no wood band should exist in them, but that the union of the materials should be accomplished by a cement which, neither by exsiccation, by frost, or by moisture, shall shrink or perish, for it will be a waste of effort to employ artists' labour on substances which will neither resist the ordinary effects of time or accident. Perhaps it may be said, that when walls have become settled, as it is called, that little danger can arise subsequently. This, however, is not always the case, as some seasons (in this country especially,) have very injurious action on buildings, and many salts escape from sands, stone, and lime, little expected by architects. Now, in properly burned, properly combined, and properly worked mortar, (the solid ingredients of which have passed through fire,) little change need be calculated upon; hence it probably is that pozzolano has been found to be the best building sand, though it is true that that which is imported is frequently brought from the shore of the Mediterranean, where the sea water has been, wherefore it necessarily partakes of the variable quality of the salt, and consequently is inferior to that fabricated of our own earths properly prepared and selected.

To return to the paintings exhibited:—it is hoped that the Institute will make allowance for their being merely experimental. Doubtless, much improvement will take place, should there be made any future attempts: as they are, they will perhaps show, that for such a city as London, the mode used is proper and cheap for decorative and historical painting; that the substance is, as well as the paintings, of a permanent nature; that the surfaces are such as neither to harbour dust or dirt; that they are easily cleansed, and can be employed for the most magnificent and talented displays of the efforts of our rising artists.

ON EARTH WORK, EXCAVATION, CUTTING, AND FORMING EMBANKMENT UPON RAILWAYS.

ARTICLE I.—GETTING, FILLING, AND TIPPING.

"Modern practice has reduced it to a price per cubic yard."

Professor Vignoles' Lecture, Dec. 1841.

SIR—I need not occupy your space in any introductory remarks on the importance of the price per cubic yard for earth work, both to the profession and the public, and with your assistance I will endeavour to show what it is on a medium cutting, or what in the execution can be taken off at a single lift, when the material is common earth, the eye of practice alone is able to proportion the cost when the material is of a harder or more obdurate nature. I shall fine my present remarks to the quantity that can be moved or carried into embankment per man per day from the cutting, the rate of wages of the excavator at the time will then show the cost of getting and filling. The cutting I am about to describe was in the line of railway, or what is called *back-cutting*, in contradistinction to earth got out of the line, which is called *side-cutting*, it consisted of good gravel, covered with a varying depth of vegetable mould, and a small quantity of brick earth, and would average in depth 14 feet, and one mile in length, and was used to fill a valley of similar extent. The wagons used were estimated to contain $2\frac{1}{2}$ cubic yards each. The men were counted four times each day, and the average taken on the number of men employed. The wagons also were counted daily. The time of year was the most favour-

able to show the action of change of weather on the result, also the effect of thaw after frost in assisting the operation of the excavator. In the first column is the date, in the second the number of days' work made in a week, which divided by the days will give the number of men. In the third column are the number of wagons of 2½ yards each carried into embankment, and in the fourth column the number of cubic yards moved per man per day in the excavation.

1837	No. of days work.	No. of wagons.	Cubic yards.	
Jan. 7	348	920	6½	
14	291	831	6½	
21	354	950	8	
28	189	466	8½	Hard frost, thermometer 20° below zero—work limited on account of tenacity of earth.
Feb. 4.	85	171	5	
11	232	733	8	
18	359	1147	7 nearly	
25	419	1140	6½	
Mar. 4	458	1630	9 nearly	Work easier on account of thaw.
11	458	1440	8 nearly	
18	387	1238	8 full	
25	458	1263	7 nearly	
Apr. 1	463	1276	7 nearly	
8	479	1569	8 full	

The quantity removed and carried into embankment in one tip was nearly 400 cubic yards per day, which I consider very fine work. The width of cutting at the formation level was 31 feet with slopes of two to one, and the width of embankment, out to out at top of slopes, 34 ft. 6 in., which would confine the deposit to that width, as the embankment was carried to the full height of bottom of ballasting at once, and not in layers.

From the above table it will be seen that eight yards is nearly the quantity moved per man, and if the wages be 3s per day, the price per yard will be 4½d, which is the fact under the circumstances above stated. The work was carried on vigorously, but not pushed night and day, and every modern operation was taken advantage of, viz., gulletting, falling the earth by gravity over a bench left in the bottom for the purpose. The difference between the expence of excavating in side cutting out of land not in the line of railway is a small fraction cheaper, but the amount in value of plant is greater.

The above gross results are more satisfactory to my mind than the most careful division of the men into getters and fillers, as whoever has seen a work in full operation must be aware that some are gulletting, some filling, some carving under, and some filling into wagons, others wheeling at top with barrows, some casting out at bottom, and all contributing their mite to the same set of wagons, and in many instances to the individual wagon. I cannot omit to mention that I found my results exactly to coincide with those of Mr. James Day, in his Treatise on the Construction and the Formation of Railways, who states eight cubic yards as the average that is cut and loaded by each individual; his maximum having reached to twelve, and his minimum to six. In the detailed account of how much per man excavated you will find that my minimum is one only less than Mr. Day's, and that minimum was on account of the extraordinary frost; but that the ratio of my minimum amount to his is much smaller than in the maximum, his being twelve, and mine only nine, and that in only one instance. Mr. Day does not state in what period of the year his observations were made, nor in what year, or the nature of material, he only states that the locality was Durham; my observations were made on a portion of the Great Western Railway in Buckinghamshire. Mr. Day's book reached a 2nd edition in 1839, and I believe is the only writer who has entered into much detail, which, however, he does not give.*

The lectures of Professor Vignoles at the London University College,

* I do not think any information in detail is to be found in the "Public Works of Great Britain," the "Transactions of the Institution of Civil Engineers" (who have however this year attempted to remedy the defect by offering a Telford Medal on the subject, viz., on the various modes adopted for moving earth in railway tunnels, cuttings, or embankment, with the cost thereof), in the "Papers of the Corps of Royal Engineers," "Wood on Railways," "Tredgold on ditto," "Brees' Railway Practice," the "Book of London and Birmingham, and Grand Junction Railways," the "Railways of Great Britain and Ireland," or indeed in any book professing to treat on the subject, excepting the one already mentioned.

Much time would be saved to parties entering on a new course of study if individuals connected with any particular subjects for study, would communicate the results of their reading and practice to each other. A bold attempt to carry out this is being made at the Literary and Philosophic Institution of this town (Newcastle-on-Tyne.)

reported in the Journal, at the commencement has had a powerful effect, and I hope his wishes expressed in his first lecture will be accomplished. "To popularize the knowledge of engineering as a means of benefitting the public at large."—(C. E. & A. Journal, Feb. 1842.)

I have introduced the above remarks, although a little irrelevant to the subject, knowing as I do the prejudice that prevails against scientific knowledge. I will now proceed to notice the relative quantity of earth removed by estimation of the wagon at 2½ cubic yards, and by measurement with the tape. In the period from Jan. to March, 19,660 cubic yards by measure were removed, and 23,570 cubic yards by wagon; from Jan. to the end of March 28,834 cubic yards by measure were removed, or 29,912 cubic yards by wagon; the wagon being in excess both for the long and short period, but not in a greater ratio than it would be were too indifferent parties at different times to use the tape; indeed, 2½ cubic yards per wagon was so well established, that the men were indifferent whether they agreed per yard or per wagon, the price paid per wagon was 10d. Another coincidence which show that the foregoing remarks are founded on sure data, is that 2½ cubic yards at the rate of 4½d. per cubic yard nearly agrees with both the yards per man, and the rate of remuneration and estimated load of each wagon.

The following table will also be instructive, as showing the proportionate effect of small or large gangs of men on the quantity turned out. I will not specify the times *seriatim*, but merely observe that it was over the same period as the former table, and the same wagons were used. In the first column are the number of men employed at one time, in the second the number of days, and in the third the number of wagons employed, and in the fourth the price per cubic yard.

Men.	Days.	Wagons.	Price per yard.
15	5	140	4½d.
72	4	846	7 upward
74	1	192	6 above
74	4	761	6
75	4	847	7
80	1	240	7½
83	4	1045	8 above
80	4	742	5½
86	1	248	7

From the above table it will be seen that, like all questions, this has two sides, viz., that the hurried work cost the most money, and that when the work is not carried on with sufficient vigour, the same effect is produced. The price of 4½d. will be seen is a fair estimate when the work is carried on with a fair proportion of hands. The sub-contractor or gauger was paid 6d per cubic yard, for which he had to superintend the navigation and the finding of shovels, tools, and sharpening picks, advance the men money when come off *tramp*, lay down the temporary road, including turn-outs, shunts, crossings, boxes, spurrings, &c. take up and relay the road at the gullet and tip-head, as the work advances both in the excavation and the embankment, and to keep the road in repair, and tip or turn the dirt. The price he paid for tipping was 13s. 6d. per hundred wagons, or nearly ¾d. per cubic yard, leaving ¾d. per yard for roads, and ¼d. for superintendence. He was advanced subsisting money weekly, after the rate of 2s. 6d. per day per man from the time-keeper's return, and his work measured every fortnight. There being the following checks, viz., time, tape, and estimated quantity per wagon: out of the ¾d. per yard, the price of keeping up the road, ¼d. per yard, was retained in hand as security until the final measurement at the completion of the cutting. The price of 6d. was for the bulk of the excavation, some portion of the bottom, say three feet, in depth, being taken up back-handed (that is, as the work was cleared up, and the temporary road taken up) was paid for at the rate of 7½d. Again, at the commencement of the cutting at the balance level, where cutting and embankment commence, barrows were used for a short way into the hill before the rails were laid and wagon-work commenced, the prices varying from 3d., 3½d., 3¾d., 4d., 4½d., 5½d., 6d., and 7d., the latter being for a distance of about sixty yards, barrow-work being rated at about 5d. per cubic yard for the first run of 20 yards, and 1d. per additional run, when the tenacity of the earth requires no getting, so that the earth can be as easily excavated as refilled.*

Again, the top surface of cuttings and the seat of embankment are usually uncalled for the purpose of reooling the slopes. The uncallowing and

* A run is 20 yards, allowing for the inclination, although when on descending ground it is taken at 25 yards, but in most cases the level and ascent or descent, are computed as equivalent, and 20 yards is used as the measure in practice.

rescoring together, not each separate operation, must be taken at the lowest price of 3d. and 3½d. Setting the above low price and the greater price of 7d. for the barrow-work against each other, and taking into consideration the comparative small cubic quantity of each in comparison with the bulk or body of the cutting, I do not think that the medium price of 6d. will be materially influenced. Furthermore, the effect of the gradually increasing "face," or depth of the hill from the balance level of cutting and embankment to the summit acting in favour of the operations of the excavator, will also much tend to equalize the two prices.

In conclusion I will glance at what you have already done in your Journal on the subject of earth work, which I think will more fully shew the value to the public and profession of the preceding tables, and the correctness of your views in the review of "A Practical Inquiry into the Laws of Excavation and Embankment, by a Resident Assistant Engineer," in the *C. E. & A. Journal*, vol. iii, 1840, p. 391, to which I most respectfully call the attention of your readers; as also to vol. iv., p. 417, where the performance of the American horse-scoop is noticed, and the quantity removed an average distance of 34½ feet per scoop per day, is stated to be 40 yards, and the cost 4½d. to 5½d. per cubic yard, rating the hire of scoop and driver at 12s. 5½d. per day, each scoop contains ⅓ of a cubic yard; also to page 59, vol. v. for 1842, where Professor Vignoles in his 5th lecture, on earth work, states that "the causes that have thrown the railways of the Continent into the hands of the English contractors to be the 'finical exactness with which they (the French) calculate the expense of removing the first 100 yards, then the next 25 yards, and so on increasing until they get to 300 yards, beyond which the price is enormous.'" This will form the subject of my next communication, and for the present I subscribe myself, with sincere thanks for your former kindness, to be,

St. Ann's, Newcastle-upon-Tyne.

Yours obediently,
O. T.

ON ARCHITECTURAL CRITICISM.

SIR—A knight, who has just entered your lists with his vizor down, having *en passant* permitted me to hear a little harsh voice, which it may be can sound agreeably, I have thought it quite as well to whisper a few words in his ear; not because, under the notion that he disesteems me, I would descend to parley, but because from his appearance and "*attitude*," I am quite sure I should be addressing one to whom the affectation of contempt is more natural and becoming than would be the reality of that feeling.

Changing then my position, I had thought that no one, who presumes to love abstract speculation, would deny, that however deficient my papers may be, however in their *direct* tendency they may bow to the very able paper of H. S., yet, that upon that most delicate tissue of thought—the philosophy of taste (out of which emanates so much that is refining to us as students), I had not disgraced my subject, and that in an attempt to establish the poetry of an art which I love, I could have done no less than discuss those elements from which our emotions arise. My reasons for commencing the "Hints on Architectural Criticism," were upon the showing that critics very often deluded, by their weak and capricious opinion, the art they professed to extol, and that, as a consequence, that art was held inferior to the art of the sculptor and the painter, and so in order to elevate our art, I found that the philosophy of our claims to the rank of a fine art should be clearly made out, otherwise we should be in the same position as we were.

It is upon these grounds that I have tried to show how those arts which are not descriptive may maintain an influence over the emotions.

If J. L. will tell me that he is indifferent to my attempt, I must I suppose believe him, but I cannot help thinking that as a lover of art he must know, (whatever he admits) that the more we can establish the philosophy of our claims to a rank disputed by many, and the more our inferior critics see and feel the foundation of our claims, the more honourable will be the defence of our art.

I only ask, Sir, of J. L., disguised as he is, not to show his dislike in the ignorant and common way of sneering at what (he says) he does not understand, but to dispute in the manner of a gentleman for that truth which, as a gentleman myself, is all I wish to establish.

I am, Sir,

Yours very obediently,
FREDERICK EAST.

Feb. 9th, 1842.

ON STAIRCASES.

To the Penny Cyclopædia we are this month indebted for an interesting architectural article, upon the subject of staircases, which not only contains very far more information than is to be met with in any other work of the kind, but a great deal of excellent original comment. Hitherto encyclopædia articles of this class have usually been very meagre and unsatisfactory, and have consisted of little more than compilation and repetition, without any attempt to supply pre-

vious deficiencies. The Penny Cyclopædia, on the contrary, displays unusual carefulness of execution in its architectural department, and in the articles of architectural biography, in proof of which we have only to refer to *Ohlmüller, Oriol, Portico, Pulvis, Badriguez, Roman Architecture, Rotunda, Rustication, Saloon, Sansovino, Scagliola, Scamozzi, Skylight, and Soane*. Very few of these have till now obtained any notice at all, unless a brief definition of their meanings deserves to be so called; nor is it always that even that is to be found. In this respect, therefore, the Penny Cyclopædia manifests a very great improvement upon all its predecessors. Nevertheless there might be some additions and enlargements; and we would suggest to the proprietors of the work, that, on its completion, all the architectural articles (including the biographical ones,) should be collected and reprinted in a separate form; and when we say reprinted, we do not mean verbatim, but that they should be revised and extended, and illustrated with additional drawings. Were this done, we should have what is still a desideratum—a good architectural dictionary; in which opinion most of our readers will, we think, concur with ourselves, after perusing the annexed extracts from the Penny Cyclopædia.

"It was not till about the time of Elizabeth that staircases began to be planned more commodiously in this country, and made a decorative feature in the interior of a mansion. But though they were greatly improved, the flights being made wider, and the steps parallel to each other, with intermediate landings or resting-places between the several flights, and although considerable decoration was bestowed upon them, the walls being panelled, and the parapet of the stairs formed either by richly-carved balusters, or open fretwork, frequently with heraldic figures of animals on the pedestals at the angles of the different flights—the staircase itself was usually enclosed within a comparatively small area, so as to admit of no general view of the whole of it, there being very little open space, or *well*, as it is termed; sometimes none at all. The staircases at Aldermaston, Berks, Crews Hall, Cheshire, and Knowle, Kent, may be taken as examples of the kind. At a later period staircases in mansions of a superior class were made disproportionately spacious, being upon a scale as to size with which the apartments themselves were not at all in keeping.

"The planning of a staircase is generally considered one of the most difficult matters in internal architecture, and it is certainly one that requires great consideration. Yet there is no particular difficulty, except where, as is generally the case in moderate-sized houses, the architect is cramped for room; more especially if, while restricted in that respect, the ascent from one floor to another is greater than usual. The number of stairs and the space required for the convenient arrangement of them, are easily estimated when the height of the ascent from one floor to another is given, and the dimensions are determined for the risers and treads. Stairs are technically described as consisting of *Risers* and *Treads*, the former being the fronts or heights of the steps, and the other their flat surfaces or breadths. Stairs are further distinguished as being *Flyers*, those which ascend straightforward; and *Winders*, which having their treads triangular, coming quite to a point at their ends next balusters, afford no footing there, and ought consequently to be avoided whenever it is at all practicable to do so. A *Flight* is a consecutive series of stairs in the same direction, or between one *Quarter-space* or *Half-space* (*Palier de repos*) and another, which last are short intermediate landings, serving to lessen the fatigue of a continuous ascent, by subdividing it into shorter flights. For the area containing, or rather constituting, the staircase itself, we have no distinct term in addition to the general one, similar to the French *Cage*, the Italian *Gabbia*, and the German *Treppenhau*.

"We proceed to notice the most convenient proportions of the stairs themselves, as to height and breadth, for their length. As to the breadth of the flights, that is comparatively arbitrary: it should never be much less than four feet, so as to allow two persons to pass, except in back-staircases; but it may be as much more as the space will permit, or the effect aimed at in the design may require. The best general and what may be considered standard proportions, are 6 inches for the risers, and 12 inches for the treads; though from 6½ to 7 inches may be allowed for the former, and only 10 for the latter, in secondary staircases. In those of a very superior kind, on the contrary, the risers do not exceed 5 or even 4 inches (less height than which last would be more fatiguing than convenient), and their treads are then made from 14 to 16 inches. The height, therefore, to the landing of the floor to be reached being given, it is easy to calculate either how many risers of a certain number of inches will be required, or what must be the dimensions of the risers and treads, in order to ascend within the space allowed. Supposing the first-mentioned height to be 14 feet, and the risers 6 inches, two risers will be equivalent to one foot of ascent, and consequently twenty-eight risers will be required, or twenty-seven treads, the upper landing being the tread to the last

riser. In such case, hardly less than an area of 20 by 8 feet, on the level of the upper floor, would be sufficient for the staircase, unless there were winders instead of quarter-spaces, or of a single half-space between the two flights. The number of risers required is ascertained by reducing the given altitude of ascent to inches, and dividing it by the height of the risers: thus, taking the altitude as before (14 feet), and the risers at 5 inches, there must either be 33 risers a trifle more than 5 inches each, or 34 a trifle less.

* Palladio, and others following him, have laid it down that the staircase ought to be seen immediately on entering a building; but it is impossible to establish any positive rule for what must depend upon particular circumstances, and this is by no means the best as a general rule. In a public building, or place where strangers go in and out without inquiry, it may be desirable that the staircase should present itself at once; but certainly this is not the case in private mansions. On the contrary, it is in every respect better that the staircase should be kept out of view until the first vestibule has been passed through, and that it should be placed as remote from the entrance into the house as the plan will admit, both in order that the approach to it may be lengthened, and that, in case it has any architectural pretensions at all, it may strike the more by not coming into view at once. At all events, only the lower part of the staircase—no more than is sufficient to indicate its situation—should be visible from the entrance, otherwise it will be inconveniently exposed; and if there are doors to several rooms on the upper landing, persons passing from one to the other would be seen from the hall. It is, therefore, a great error to place the staircase, as is sometimes done, in the first or entrance hall of a mansion, because, in addition to the inconvenience just pointed out, such hall must be made the height of two floors, and consequently, if otherwise suitably proportioned to such height, it will be the most spacious and loftiest room, and so far be attended by a degree of effect which, instead of being afterwards increased or kept up, is greatly diminished. Such arrangement also cuts off the communication above between the rooms on one side of the hall and those on the other, except there is a gallery or continuation of the landing carried over the entrance."

* * * * *

"One of the most simple and effective yet least common arrangements of a staircase, is that which may be described by the term *Avenue staircase*, the stairs being continued in a straight line, though broken by spaces into a succession of flights, within what would else be a level corridor or gallery, and occupying its entire width. There is something particularly noble and majestic in a staircase of this kind, for although it may be narrow, considered as a gallery, it looks unusually spacious as a staircase, the flight itself being wider than those of staircases placed within a much larger area. Besides which, the whole is more regularly disposed, and forms a more striking piece of perspective. Still simple as such plan is in itself, it is by no means adapted to general application, because, although it requires only moderate width, it requires considerable length, short flights, and ample spaces between them, and stairs with low risers and broad treads; otherwise the descent as viewed from above, being in a straight line, looks precipitous, or at least has no dignity of appearance. Another circumstance which limits a staircase of this kind to particular cases is, that in order for it to produce proper effect, the height to be ascended should be very moderate, hardly more than seven or eight feet; for else the space at the foot of the stairs looks confined, and the upper flights scarcely show themselves from that station. Hence, though it may be referred to as an instance of an avenue staircase, the one leading to the keep or round tower at Windsor Castle is more remarkable than beautiful or grand, leaving decoration out of the question; the altitude ascended being so very great. Sir John Soane has given some ideas of the kind in his designs for a "Scala Regia,"—a favourite subject with him; and he executed such a staircase, though upon a more limited scale, for the royal entrance to the House of Lords. The width of that staircase is only 10 feet, by 49 in extreme length, and the ascent 9 feet. Though not free from little conceits, the whole has considerable effect, as may be judged from the perspective view of it in vol. I. of the "Public Buildings of London," by W. H. Leeds, which also contains a longitudinal section of it. The staircase of the Chamber of Peers at Paris, designed by Percier and Fontaine, is another example of the kind, upon a larger scale, but not the very best, for the ascent is so great, that the columns on its sides, on the same level as the landing, look quite insignificant. That at Covent Garden Theatre also belongs to the same class, although it differs from the preceding in being extended in the upper part, by the landing being continued along its sides as a gallery divided from it by columns; the ascent is about 10 feet, in two flights. The National Gallery, again, affords instances of a different modification of the same arrangement, half the ascent being by an external flight in

the vestibule, the remainder by another within the corridor leading from it; and though not exactly suited for such a building, the idea is pleasing in itself, and would produce a striking effect in one of less pretension.

"In public edifices or large mansions, whatever be the plan of the principal staircase, it is generally *branched*, that is, there is first a wide central flight, and then two other narrower ones branching off from it, one on each side, either at right angles to it, or as return flights parallel to it; and it is hardly necessary to observe that in all such staircases the foot-spaces are large, and that there are no winders. The staircase at Goldsmiths' Hall, which is parted off from the vestibule by a glazed screen, is an example of more than ordinary splendour, being lighted by a dome. The branching flights at right angles to the first, lead to a landing on each side, which has a double screen of Corinthian columns, so that the view across from side to side, in the upper part, is unusually rich. At Buckingham Palace, there is first a very wide flight, entered from between columns, branching off right and left in curved flights, the cage, which is about 36 by 26 feet, being curved elliptically on those sides or ends. In this example, the stairs rest upon a graduated podium or wall enclosing the space immediately beneath, which serves as a private passage behind; a mode frequently adopted in similar cases, being one which contributes to solidity and nobleness of appearance, and prevents that mass of shadow beneath the stairs which gives a gloom to the lower part of the staircase."

* * * * *

"The staircase of the Fitzwilliam Museum, Cambridge, claims notice, not only on account of the richness of the general design, but of some peculiarities in its arrangement. Strictly speaking, however, this example can hardly be given as that of a staircase, according to the usual meaning of the term, the stairs being mere flights of steps in the entrance-hall. That in the centre is a broad descending one, leading down to the libraries, which are on a lower level than the hall; and on each side of it is a rather narrower ascending flight to the spacious landing carried around three sides of the hall, and serving as a statue gallery. Though the lower area is only 32 by 26 feet, consequently that of the floor very much less, owing to the space occupied by the flights of steps, that of the upper part on the level of the landing is 68 by 44 feet, the landing itself being about 17 feet wide. In some degree similar in plan, although very different in design, is the hall at Holkham, the seat of the Earl of Leicester, which has a noble flight of steps within a recess or tribune, enclosed by columns, which are continued along the sides of the hall.

"The grand staircase of the Reform Club-house, London, is an example, somewhat unusual in this country, though common enough in Italy, of what may be called an *enclosed staircase*; the flights are shut up between walls, and consequently there is no open well, nor can the whole be seen at one view. A plan of this kind, therefore, differs from the avenue staircase, merely in not being carried straightforward, but either returning in a parallel flight from the half-space or first landing, or having the second flight at right angles with the first. The last is the case at the Reform Club-house, where the staircase consists of three enclosed flights, the last being a return one to the first, and landing upon the gallery around the upper part of the inner hall or saloon. That at Barleigh, too, is similarly planned. The same mode may be adopted for circular or semicircular as well as rectangular plans; and one advantage attending it is, that, while the ascent itself is as spacious and commodious as if the whole were entirely open, there may be a secondary staircase for servants, shut up within the larger one."

* * * * *

"The architectural effect of a staircase will greatly depend upon the mode of lighting it. Where it is carried up only one floor, the best mode is to light it entirely from above, either through a dome or lantern in the ceiling, or by making the upper part of the walls just beneath the ceiling a continued lantern. If there are windows on the landings of the several flights, the effect will be improved by their being filled with stained glass, especially if towards a back court; or, if a conservatory can be carried out on the level of the first landing, so as to show itself through glazed folding-doors, a very pleasing and cheerful effect is obtained, even though the conservatory itself should be hardly more than a glazed viranda. As to material, stone is greatly preferable to wood for stairs, if only on account of greater security in case of fire; in lieu of stone, cast-iron may be employed. Marble is very rarely used for stairs in this country, and whenever it is, it should be left unpolished on the treads, or it would be dangerous to descend them. The same remark applies to stairs of wainscot, unless they are carpeted nearly their entire width."

NAVAL ARCHITECTURE—STEAM VESSELS.

WE have, at very considerable trouble, formed a complete Table of proportions of the whole of the timbers, with but few exceptions, used in the construction of Timber-built Steam Vessels. We believe that this table is the first of the kind that has appeared in print, and doubtless it will, we hope, prove a valuable acquisition to all parties connected with steam navigation, and become a model for forming similar tables of other vessels.

The "Royal Tar" and "Don Juan" were built for the Peninsular packet service; the first vessel is now on duty, and running between Southampton and Gibraltar, the other vessel was lost. The specification of the West India Mail Packets is very deficient; we understand that those built for this service by different builders vary in their proportions, excepting such parts as are described in the table.

ABBREVIATIONS.—mat., m., material; No., number; diam., diameter; th., thickness; mo., moulded; qr., quarter; A. O., African Oak; Am. O. American Oak; E. O., English Oak; E. E., English Elm; A. E., American Elm; D., Dantzic; M., Memel; N., Norway; R. P., Red Pine; Y. P., Yellow Pine; P. Poplar; P. D., Prussian deals; I., Iron; C., Copper; Perpen., Perpendicular.

All the figures which are not represented as feet or numbers are inches.

* All topmasts should be one inch in diameter for every yard in length in other words, their diameters should be one thirty-sixth of their length. The same proportion holds good for top-gallant masts.

Yards are proportioned as follows: namely, lower yards seven-tenths of an inch for every yard in length; top-sail yards five-eighths of an inch; and top-gallant yards six-tenths of an inch.

PROFESSOR HOSKING'S LECTURES ON THE PRINCIPLES AND
PRACTICE OF ARCHITECTURE. KING'S COLLEGE, LONDON.

INTRODUCTORY LECTURE, January 24th, 1842.

IN the remarks with which I introduced my course on the Arts of Construction, last year, I intimated how much more extensively the term architecture applies, and how much more is embraced in the complete practice of architecture than is generally inferred from it, or understood from its application. I considered my duties then to be restricted to the consideration of the technical combinations of matter to form constructions, but I have now to treat of the mental skill and the regulated taste which direct the employment of the arts of construction, and of the means of acquiring such skill and taste, and of applying them in practice. These, together,—the mental skill to arrange and adapt, the technical knowledge to construct, and the regulated taste to dispose and decorate,—form the architect, and the result of the combination in his productions is architecture. The best constructions applied unaptly, or incongruously disposed, the most skilful arrangements for use, unsymmetrically disposed, or inconsistently decorated, or the most classically disposed and chastely decorated exterior to an ill-contrived plan, are alike unworthy the name of architecture and the reputation of an architect. Unless the arrangements for service and use are the best that the case admits of, unless the constructions are perfect in themselves and in their combination, be the materials what they may, and unless the dispositions for decoration, and the decorations themselves, be well proportioned and consistent, a work is undeserving to be distinguished as architecture. There must be excellence in letter and in spirit, in form and in substance, to constitute an excellent work of architecture, and it is only those who combine in themselves the skilful arranger, the tasteful disposer, and the sound and economical constructor, who can claim the character of architect.

The general acceptance of the term architecture is in its most restricted sense, the decorative disposition of buildings, or that which I refer to the regulated taste of the architect; but this is to take the chased and enamelled case for the watch, or the setting for the jewel. A quaint and often quoted writer of the 17th century says truly, that "the end of architecture is to build well," and that "well building hath three conditions, commodity, firmness, and delight." All these conditions, I have already said, must be fulfilled to constitute architecture, and more must be understood by them than the

mere words in which they are expressed would appear to convey, but not more than they really imply. All the operations, of whatever kind they may be, necessary to the perfect fulfilment of those conditions, are included in the system of architecture, and consequently fall within the province of the architect to originate and direct.

I endeavoured, on the former occasion to which I have alluded, to indicate the line that might be drawn between the architect, commonly so called, and the civil engineer, constituting the latter the hydraulic architect; but the first step the architect finds himself called upon to take, the first subject that claims his consideration in any work that he may be employed upon, is strictly within the practice of hydraulic architecture, so that if the architect be not also, not merely informed, but skilled in that branch of practice, he is unfit to take the first step, to undertake the consideration of the first subject that presents itself in commencing the process of building well. An architect may be called upon—and who so competent as a thoroughly accomplished architect?—to choose or select a site for a town—or more commonly intrinsic circumstances, some peculiar advantage or advantages it may possess, in a commercial point of view or otherwise, dictate the site, and it devolves upon the architect to fit the site for the purpose to which it is devoted. Easy access by roads, which roads must be laid out and set out with proper inclinations, and with bridges and culverts to carry them over streams and gullies, and they must be cut, formed, drained, ballasted, and metalled, or otherwise paved; quays to the river or the harbour must be arranged and formed or embanked, and constructed, encroaching upon the tideway or widening the waterway, as the case may require; or, in the absence of natural facilities for navigation, it is a question for consideration and determination—can artificial navigation be obtained, and how and in what manner shall the site be best disposed of to take advantage of it? The site of the town must be drained, and the soil drainage taken off, roads as streets and open places within and about the town, must be laid out and disposed in such manner as to be best adapted for the buildings to be erected in and about them, and generally as to light, aspect, and ventilation; water must be led to, or raised by artifice within the site of, a town, and accumulate in reservoirs, from which it may be distributed for use and enjoyment. Many of these things may, indeed, be referred to the engineer or other extraneous practitioner, but most of them are generally left to chance, or to be created or corrected when the hard teacher Experience has pointed out what ought to be, or to have been, done. It may not happen, indeed, to very many to have towns to originate and design, but, almost every building or cluster of buildings—a nobleman's mansion or an establishment for manufacturing or other commercial purposes—a plain country house or a county asylum—a church or a palace—all make some demand, greater or less according to situation and circumstances, upon the skill of the architect in hydraulic works and constructions, and consequently demand, of every one professing himself an architect, perfect competence to originate and execute them. With reference to these considerations I may remark, too, that the widely extended and daily extending and improving colonies of this empire present a wide field of employment to the architect and engineer, and where every thing will be required of the practitioner single handed, or rather where he will be well and beneficially employed only if he can turn his hand to every thing—to drain a marsh as well as to raise a column, to build a church or a town-hall as well as to make a railway or to form a canal.

It is not often, perhaps, that the civil architect will have occasion for a knowledge of military engineering, but it is very desirable that he should be able to work with the military engineer, or rather, with reference to what the military engineer would deem necessary for the defence or protection of a town, whether from external force or from internal commotion, and to know how to make his arrangements accordingly. Gates and guard-houses are not of common occurrence amongst us at home, truly and happily, but such works are not the less in demand in some places, and the architect who might be called upon to assist the military engineer with the constructions that he may not be architect enough to design and direct, or to act in the absence of an efficient officer of that class, would be most unfitly prepared for the varied duties of active professional life, if he were then and in either case found wholly wanting.

An architect should, then, have an eye to defences and defensive erections in laying out towns of certain kinds and under certain circumstances; he would act unwisely to place a wharf or a landing-pier or jetty in that part of a harbour where a battery may be essential for its protection, or to raise buildings that would intercept the fire of a fort whose guns should range across their site.

The architect will be called upon for the exercise of skill and taste, guided by a thorough knowledge of the peculiar requirements of every class of a community, and of the community as such, in the distribution of the parts of a town, and of the various public and private erections and establishments that every civilized community requires, and especially with reference to the peculiar circumstances of the particular town and community. There must be public places, as open markets or otherwise, in or upon which some of the requisite public buildings may open and display themselves, and where fountains form ornamental and appropriate objects, and public places as parks and gardens for exercise and recreation, sites for public buildings, sites for the varieties of private dwellings, and places for manufacturing and commercial buildings and establishments according to their kinds and requirements. These are all to be provided and arranged to produce the greatest possible general convenience and advantage; and towards effecting this, the relative

levels of the lowest floor of the buildings to the drainage level, together with the requisite provision for general ventilation, should all be settled, so that it be not left to chance or to the ignorance or caprice of individuals in building in detail, whether the town shall be pleasant and wholesome, or be the seat of discomfort and disease.

Operating in detail, the architect will have to study closely the means of securing what must be deemed essentials to every building. There must be convenience and facility of access to the building itself;—relief from water must be secured in every direction, and in whatever form water can present itself, from the earth or from the skies, by the foundations or by the roofs, and with this the relief of every building in which such can arise, of soilage, must be fully provided for; the admission of air is to be regulated and brought under control, to ventilate without establishing injurious draughts; and light is to be admitted and diffused so that every part of an interior may be appropriately and sufficiently lighted, and lighted from a general source directly, or with as little recourse to borrowed and artificial lights as possible; equable temperature throughout the varying seasons is to be maintained by the exclusion of excess of heat at one season, and by the promotion and diffusion of heat to warm at another; and perfect facility of intercommunication to the fullest extent that intercommunication may, in each particular case, be desirable, between the parts of an interior, whatever may be the relative levels of the parts, or at whatever distance they may be from one another.

Next to the general essentials, which are as much so to a Penitentiary or to an Hospital as to a Palace, are the particular arrangement and distribution of each peculiar class of buildings. This does not admit of general definition, but to take one and a large class of buildings—dwelling-houses,—and their congeners, buildings which include offices for state, as palaces and other official residences, and houses which include offices for service, as professional, mercantile, and commercial houses, as well as domiciles:—every building of this class may be resolved into three departments—the public and the familiar or social,—the private,—and the domestic or economic; all being alike severed and connected by means of halls, vestibules, courts, corridors, passages, and staircases, and so that every apartment may be at once secluded and accessible, and without destroying the power of secluding or of making accessible every other whose use demands one or both of these qualities.

The economical composition of a building, with reference to the materials to be employed, in drains, foundations, walls, partitions, floors, roofs, ceilings, stairs, doors, windows, chimnies, and all other essential and accessorial details, with the details of their construction and combination as to quantity and quality of material, and the proportion of each particular kind, and the nature, quality, and extent of work or labour required, or to be employed in constructing and combining the materials, is an important part of the study of the architect. The basis of this study—the arts of construction—I treat of in another course addressed to both architects and engineers, but in the practice of the architect the economical composition of materials involves the application of the arts of construction with a multiplicity of detail unknown in the ordinary practice of the engineer or hydraulic architect. There is not only the formation, construction, and fall of drains, but their ramified distribution to take off both water and soil drainage, and to make the water act upon the soil to scour it away; supplying water, too, sufficient to effect this from some certain source, trapping them in such manner as to cut off and prevent the return of offensive smells, arranging so as to render them easily accessible for repairs, and in arranging to avoid running them through the bases of the superstructures;—all form essential studies for the architect. In like manner with the various kinds of materials in parallel constructions, and having irregular or unequal tendencies to settle, as brick or stone walls and partitions, and partitions of timber,—brick walls and stone stairs set in them;—these, and numberless other things in the ordinary practice of the architect, call for the exercise of much forethought and consideration in the economical composition and combination of materials, where the unpractised observer would not discern a necessity for either, until the effects resulting from the want of both, and of sound practical knowledge to guide them, are displayed in bulged walls, cracked ceilings, rounded floors and doors, sashes and shutters that will not shut when opened, nor open when shut.

The particular arrangement and distribution of buildings according to the purposes for which they are respectively required or intended, to adapt every kind of building to its special use, demand that the architect be of ready apprehension, and that he possess ingenuity in devising, combined with skill in constructing; for practice will more frequently require him to make his plan to fit the place than supply a place to receive the building as he might prefer to plan it, and he will thus be called upon to invent arrangements in almost every particular case, to secure what is required in the manner best adapted to the circumstances of the case. The uses of buildings are, indeed, so various, and the requirements of each particular use so different from those of every other, in all the classes of buildings,—every individual building of a class requiring or possessing peculiarities in site or other circumstances, and thus presenting in every case a new study,—that an architect cannot stereotype the drawings and specification of a design for any particular class of building, though rendered as perfect as the most careful study with the most intimate knowledge of his subject can make it, any more than the lawyer can stereotype his brief, or the physician his prescription, unless, indeed, the architect be,—what the physician who did so would be called—a *quack*. Every case brings to the lawyer its own circumstances,—in which he finds it to differ from every other, though the name of the process be the same; the physician finds every new patient to present something different, though suffering from the

same disease; and the architect finds the data upon which he has to work,—be the subject a church or a college,—a mansion or a cottage,—to differ for every church, college, mansion or cottage, to which his attention may be directed. The usual premises are the *subject*, the *site*, the *kind* and the *extent of accommodation required*, and the *money to be expended*. Instead of this last premiss, it would be more proper to give the kinds and qualities of materials to be adopted, and the quality of work required, as to finish and decoration, though it is too frequently expected that these shall be of the more, if not the most, expensive, while the outlay is limited, and the architect has, not only the task of adapting the subject to the site—frequently no easy task—but the further complex Procrustean operation involved in fulfilling the other conditions, which—it may not be wondered at—architects seldom succeed in doing perfectly. In the first place, and independently of site or other circumstances, and irrespective of cost, the various subjects present themselves to the architect with their varying general characteristics, and, as I have said, the consideration of these alone will show that the requirements of the classes of buildings are neither few nor easy of fulfilment, without perfect possession by the architect of all the technical knowledge and skill already indicated, and of science to guide and regulate the process; nor, indeed, with all these unless he have acquired habits of observation and possess ingenuity in the application of what he may know and observe, together with facility of invention and power of adaptation, even in the arrangement and distribution of buildings with reference to their uses only, and without any reference to decorative disposition, which last may be said to form almost a separate study.

Taking the various subjects or classes of buildings which form the common range of architectural practice, it will be seen how they justify these observations. And first as to CHURCHES. This important class of buildings demands an arrangement which will give peculiar prominence to one person—the minister—who must be brought within the eye and ear of every individual of a congregation, and enable the congregation to unite with the minister in public worship, and that without confusion from imperfect means of communication; whilst, at the same time, the largest number of persons must be brought within the smallest space consistently with the comfortable accommodation, in the varying attitudes of sitting, standing, and kneeling, of every person provided for; together with freedom and ease of access and egress to and from every part with the least possible display. In COURTS, HALLS, or CHAMBERS FOR DELIBERATIVE ASSEMBLIES, it is required that every individual congregated shall be alike visibly and audibly prominent. COURTS OF LAW, and for the administration of justice, demand prominence to be given to particular persons, as the judge or the magistrate, the accuser and the accused or their counsel, the witnesses and the jury, and so that each and every one may see and be seen, hear and be heard by all the rest; whilst a continually changing auditory must be provided for, and in such manner that the movements of unoccupied persons may not disturb or derange the business of the tribunal. TOWN and GUILD HALLS combine many of the requisites of both chambers for deliberative assemblies and courts for the administration of justice, on a smaller scale, but their compound character demands for them, nevertheless, a particular study. THEATRES, as usually understood, for the exhibition of dramatic performances, require the perfect exposition for both sight and hearing of one part to the occupiers of all the rest of their interior, with separation of the occupiers or auditors amongst themselves into classes, and some of the classes again into secluded parties, giving to all classes separate means of ingress and egress, and at all times without disturbance or confusion. Other than dramatic theatres require their own particular objects to be provided for, and all but theatres for dramatic exhibition and performance require the admission and diffusion of the light of day as well as provision for artificial lighting, which latter alone is supplied to dramatic theatres, and constitutes them singular in that important particular. EXCHANGES, or *Markets without the presence of the commodities to be bought and sold*, require accommodation for large concourses, and in such manner that people may move about singly or in groups, and thus intercommunicate without confusion. MARKETS, *for the exposure and sale and purchase of goods*. These are real and substantial Exchanges, and they may be general or special, and according as the market is devoted to one particular purpose,—when the arrangements must be specially adapted to the conservation of the particular article, as well as to its exposition for sale,—or the market being general, it must possess in different parts the peculiarities necessary for different articles;—whilst, in all, every facility is to be provided for freedom and ease of passage to the public in every direction, and all convenience of exposition for sale must be made subservient to facilitate the examination and selection of articles by buyers. BATHS, though not so much called for, indeed, in this country, as public establishments, as they may and ought to be, require much skill and tact to arrange and distribute them without loss of space, and to effect the separation and seclusion of one part from another, and to provide for the combined publicity and privacy which the use of swimming-baths—the best sort of bath—compels and demands. It would, however, be endless to rehearse in detail the requirements of every particular class of buildings, and the recital of their designations will convey a sufficient idea, for my present purpose, of their varieties, and of the demand made therefrom upon the architect for ready apprehension of the peculiar requirements of each particular class of buildings, and for intelligence and ingenuity in supplying and producing what may be required. There are buildings for FISCAL and ADMINISTRATIVE purposes in almost endless varieties:—Public,—as Custom Houses, Excise Offices, Mints, Stamp Offices, Post Offices, Offices and chambers for the departments of State, Treasury adminis-

tration, administration of the army and navy;—combination of public and private,—as the buildings of the Bank of England, and the East India and South Sea Houses in London, ordinary banking-houses, offices of assurance, and other companies administering business in public and with the public. COLLEGIATE AND UNIVERSITY BUILDINGS have certain general requirements in common, but these are few compared with the diversities that occur in them according to local, social, and other circumstances, so that arrangements admirably adapted in one case may be totally unfitted for, or unsuited in, another. Suppose the buildings of any college at Oxford or Cambridge,—suppose those of King's College at the latter university,—to have been selected as models for the buildings of King's College in London; it will be obvious at a glance, that when the site of the latter is determined to be part of that of Somerset Place, the models are of no more use in this case than a model of Somerset House, with its deep substructions, would be for a Royal Palace upon the high and open platform of Hyde Park. The combined school and hospital, as at Christ Church in London, must require buildings widely different from a proprietary college school, and so on through every variety, from the splendid collegiate buildings at Eton to the humble parish school. MUSEUMS OR CONSERVATORIES for the safe keeping and preservation and convenient exposition of various objects, demand peculiar treatment in their arrangement and distribution to fulfil the different and differing conditions,—for exposure and preservation are with many things almost incompatible with one another. EXHIBITION ROOMS and GALLERIES, whether for works of art or for productions of industry, must be arranged to suit their peculiar ends, and with direct reference to them. There is room—very great room—for improvement in the arrangement of this class of buildings, for too frequently light is admitted in such manner as to throw heavy shadows over the objects intended to be displayed, or the objects are rendered invisible by the manner in which the light is made to fall upon them, or again, the objects being placed behind or under glass, the observer finds a reflection of himself or of the skylight frames, or other apparatus by which light is admitted, instead of the picture, preparation, or specimen, which it is his object to see. It may almost be considered waste of time for a young architect to occupy himself in studying the arrangement and distribution necessary to a ROYAL PALACE, as it may be quite time enough for such a matter when the occasion shall occur, but such buildings as Royal Palaces have been wanted, and the architect has been found wanting. Moreover, buildings for combined state and service, partaking of the nature of palaces, though not royal residences, are not so unfrequently required, so that the study of even that class of buildings may not be thrown away. HOSPITALS for the sick in body, and ASYLUMS for the diseased in mind—PRISONS for the accused, and PENITENTIARIES for the convicted—BARRACKS for soldiers and ARMORIES and ARSENALS for the preparation and conservation of warlike stores—MILLS and MANUFACTORIES, suited to the thousand arts of industry—STOREHOUSES for receiving and laying up the raw material, and WAREHOUSES for the reception of the manufactured goods—SHOPS and SALE-ROOMS for the display and distribution of the various articles in a condition for use—all have their peculiarities and every peculiarity in each particular case is to be learnt and applied, so that the brewer may find that the architect can improve upon the arrangements he had deemed perfect in his brewery, and the surgeon confess that the operating theatre of his hospital is better adapted to its purpose than he had imagined possible. The largest class of buildings yet remains, and it will be found that great as the variety of requirement is in buildings distinguished as public, it is even greater in the class of DWELLING HOUSES; for although every house may be resolved into the three departments which the uses and habits of social life require,—every house having its sitting room, its sleeping room, and its cooking room,—the nobleman's mansion must have these multiplied and extended, with accessories to include all that human wants and wishes can demand, whilst the shopkeeper is content to expose his goods for sale in the best parts of his house, and to cook, eat, and sleep where his business may leave him room, and the labourer in his turn is but too glad to find his cottage so arranged by the economic skill of the architect, that cooking, eating, and sleeping, have each a separate apartment. The idea of a peasant's cottage being included in the studies of an architect may excite a smile, but if architects were more employed upon peasant's cottages, there might be less occasion for their services in building County Hospitals and Union Workhouses. With the class of dwelling-houses may be included the study of buildings which often become accessories to the dwelling-house, as stables to the mansion, and agricultural buildings to the farm-house, though, indeed, both have their peculiarities, and require much observation and careful consideration to adapt properly to their uses. Inns, hotels, club-houses, public libraries, and buildings for the use of societies or institutions for the promotion or acquisition of knowledge, with their museums, their theatres or lecture rooms, and their reading rooms, possess a mixed public and private character, and must be treated accordingly.

I include, in the course of study for the architect—to make the course of architecture complete—the particular design, arrangement and distribution of works of hydraulic architecture; for the separation of this into another branch of practice, induced in great measure by a cause to which I shall refer, has left the architect ignorant of much that he ought to know, whilst the engineer has not learnt what architecture in its complete form would teach him. There is, indeed, one class of works in particular, usually undertaken by the engineer, susceptible of being greatly improved and greatly economized, but it is through an alteration in the stereotyped arrangement which long usage has sanctioned, and the engineer-architect is not architect

enough to discover the fitness of the innovation, and architects have been such slaves to a stereotyped system of architectural disposition that they would not venture upon, if they had discovered it. I allude to bridges of masonry, of which the design may, I believe, be greatly improved, while the cost of construction is materially diminished.

The *firmness* and *commodity* of buildings being provided for, the decorative disposition, or the condition that Sir Henry Wotton distinguishes by the term *delight*, is to be considered; not that the consideration to this end is to be deferred or postponed, for if it be not present to the mind of the architect in designing for firmness and commodity—if every arrangement for strength and convenience be not harmoniously disposed and fittingly proportioned—*delight* will never be found in his work, though it be hedged in with columns, or fretted with pinnacles. It matters not what the style may be; whether the leading lines have an horizontal or a vertical tendency, the elements of beauty are the same. An Egyptian obelisk, a Grecian temple, a Roman aqueduct, a Gothic castle, and a pointed cathedral, all speak to the same effect in their different languages in this respect.

In referring to the various recognised forms, modes, and styles of design, I am necessarily called to a re-consideration of the views and opinions to which I have been publicly committed for more than ten years past, and this the more especially, as they differed from the commonly received doctrines as to authority and example in these matters; and as I have, as I believe, by means of the publication to which I allude, influenced the opinions of many of my juniors in the profession, whilst the appointment which I have the honour to hold in this college renders it probable that the effect of my opinions will have yet a still further influence upon those who may be and become students of architecture here. I have met the accustomed fate of innovators, having been misrepresented by garbled extracts from what I have said, in one quarter,—and my suggestions and illustrations have been adopted, exemplified, and put forth as his own, by another writer, who intimates in the same volume, that I shall retract my opinions when I have grown old enough to know better. The name that I was the first to suggest for the beautiful style of architecture of which we may be proud to possess the finest exemplars and the best school in practice, has been adopted and employed by many, but never, as far as my observation has reached, with the slightest acknowledgment of the source from which they derived it.

I can perceive, in what I wrote between ten and twelve years ago, many remarks that more practical knowledge, derived from longer experience, and a more matured judgment, the gift of added years, would enable me to improve in revising; but I do not find anything to retract in the opinions I expressed, or in the advice I offered. I make this statement after having again looked carefully through the writings of Vitruvius, in the English version of one of his best-qualified translators that I might not have to guess, with one of his most ardent admirers and devotees, at his Greek as at his Latin, and thereby come to a worse conclusion. I find now, as I found before, much fabulous narrative, many unintelligible or inapplicable descriptions and directions, some truisms upon the art of building, some curious antiquarian reminiscences, and some excellent remarks upon professional conduct and practice; and I continue, thereupon, to hold the opinion that I formed before I was twenty-five years of age, and published before I was thirty, and now repeat to you, that “a student would acquire as correct a knowledge of history and of geography from the ‘Seven Champions of Christendom’ and ‘Gulliver’s Travels,’ as of architecture from the existing writings of Vitruvius.”

My own treatise upon architecture will be my text-book in treating of the various modes and styles of design, and of their application in practice; but I shall prefer to illustrate my observations by reference to works in execution to any other mode, believing that I may thereby induce a habit of observation in the student, which will be of much greater value to him in the formation of his mind and in directing its application, than can ever be obtained by the in-door study of drawings and models, or by the attempt to originate and design before the mind is formed and before the judgment can be matured.

The various forms, modes, and styles of design usually recognized in architecture are generally conned by the student in drawings, and learnt by rote in copying; and the details thus acquired are often applied in practice, without a thought or an idea on the part of the practitioner that architecture consists in anything more than a repetition of those certain forms, disposed according to certain fixed rules. In truth, however, each particular style may be considered as a distinct and peculiar language; and, like a language, before a man can compose in it, he must not only learn to read and to speak it, but to think in it; and more than that, his mind must be fully imbued with the genius and spirit of the language, before his compositions in it can be rendered deserving of admiration, even when the power of original thought is present. It is not all men that can speak and write, who can speak and write *well* even in their mother tongue; they are few who can compose with ease and elegance in another than their native language; but where is the man to be found, competent to compose and to express himself with propriety in each language of all the languages that possess a literature? And where is the architect who can use with truth and freedom all the various styles of architecture? Rather learn to use one style well than many styles badly, or your Greek will be like the nonsense verses of school-boys, and your English or Pointed compositions like the English of modern novelists, larded with scraps from all the languages spoken under the sun, and alike offensive to the mere English reader, and to the judicious and tasteful admirer of all literate language, when used with propriety, with proper knowledge of their powers, and with sufficient power to wield them.

From what I have already said, it will I think appear sufficiently obvious that

the qualifications of an architect are neither few nor trivial; and that when acquired, they place him as much beyond the mere artist, as the artist is beyond the artisan. Architecture and architects suffer together, from their association in the public mind with the imitative arts, and with mere artists:—the practice of architecture is thought to consist in making drawings, and the architect to be at best but a drawer of plans! Hence the responsible duties that devolve upon the architect are quite lost sight of; the careful study required to fulfil the conditions necessary to building well—the labour of pre-arranging and specifying everything for useful service, and as to labour and materials, their proportion, composition, and combination, in detail, so that the cost of execution may be minutely estimated beforehand—the anxious care in supervising, that the work be properly executed, preparing and supplying in the meanwhile perfect delineations of the constructions and decorations in detail, and the eventual investigation of accounts;—all these things are unknown, overlooked, or unheeded, and the architect is considered as an overpaid artist—artists being linked in the same category with players, fiddlers, and dancers!

But why, it may be asked, is this so? Why are men who must have extensive scientific and artistic qualifications—who must, moreover, be good men of business, when they are properly qualified to practise as architects—and who must, withal, be in a certain condition of life, to be trusted with directing the expenditure of large sums of money—why is it that this class of men is so lightly esteemed? I have already said, that it is in a great measure because architects have sunk into mere artists: as such they are considered, and they submit thereupon to be treated in a manner that would be resented as insulting by any well-regulated profession. An architectural design is looked upon as an artist's sketch—a work of nought,—and every man, how ignorant soever, deems himself competent to judge of its merits; and the unworthy practice of architects is to submit to have their productions so considered and so adjudged. Consequently architecture, as at present practised, is not a profession for a gentleman; but it is in the hands of architects themselves to amend the practice, and if every young man entering the profession would determine for himself that it should be amended in his case—as it has for a long time been in mine—a very few years would suffice to render the profession of architecture as honourable as it is useful.

I shall have been understood to refer to the existing practice of making designs, by what is termed competition. Now competition, properly conducted, is the sure way to obtain excellence; but there are many conditions to the proper conduct of a competition. There must be perfect explicitness in the terms,—careful investigation to determine that the terms are complied with,—perfect competence in the judges to select,—and perfect honour in making the selection. But to be what they ought to be, the terms of a competition should go to the extreme degree of minuteness, and amount to an unapplied specification; every design should be accompanied by a specification of the terms applied by the author to his particular design; and every design, with its specification, should be tried by competent and trustworthy investigators, upon the specified terms. Such of the designs presented in a competition as should pass such an examination might be then examined as to their fulfilment of the conditions in *building well*, and with special reference to the existing case, and the selection made accordingly.

But where are the parties requiring designs for works of architecture who will incur the expense, and take the trouble to propose terms as they ought to be proposed, while architects will speculate upon the chances of interest, or upon the effect of a clap-trap drawing or model? where the architect who would take pains to act up to the terms—if the conditions were as I have supposed—for a mere lottery-like chance of being either re-imbursed his expenses, or paid for his labours? and where the tribunal to which designs for works of architecture could be submitted, with the remotest probability of their being examined, understood, and appreciated, in such a manner as to insure the selection of the best design? Such a tribunal is not to be found, and such an one cannot exist under the present system; and all the schemes hitherto propounded, as far as my knowledge goes—and I have not been a blind observer—are utterly inadequate to answer the true end of competition—the production of excellence.

Some would form a jury of architects, to investigate the merits of designs submitted in competitions; but the favourite project is to exhibit competition designs, that the public may judge of their merits. Exhibit Greek odes, and hieroglyphic inscriptions, and ask the public to judge of the merits of the one, and to give translations of the other! for there are as many of the public as competent to either of these things, as to judge of the comparative merits of a series of different architectural designs for the same thing.—I mean, of course, with reference to all and everything that a design should include. It seems strange, too, upon reflection, to find that in every proposition it is the architects who are to bear the expense of any proposed investigation! But who are the parties to be benefited by a competition? Surely, not the architects! Only one can have the commission contended for, and the most likely man, if there were to be no competition, is the most certain when there is one; neither is the amount of business for the profession, nor the remuneration of the successful competitor increased, by the establishment of a general concurrence. How then is it to be managed, that the public shall have the advantage of competition to obtain pre-eminent designs, whilst architects may not be degraded by submission to insult and injury? Simply thus; that architects should do as,—or rather, should not do otherwise than,—lawyers and physicians do. What barrister takes a brief, or what physician visits a patient, without an *honorarium*? Who ever saw an adver-

tisement from a town council or a corporation committee, addressed "To Barristers," asking an opinion upon a legal case in which they might happen to be interested, intimating that a copy of the case would be supplied to competitors by the town-clerk, on payment of a guinea, and that the party whose opinion the aldermen or the committee-men might think the best should have a premium of ten guineas, and perhaps be employed to conduct the case? Or who ever heard of a sick man sending for half a dozen physicians, with an offer of a guinea to that one of them whose advice he—the patient—might think the best? And why should it be otherwise with architects than with barristers and physicians?—The only way to establish and maintain "respectability and uniformity of practice" in ungoverned professions is, (by mutual consent, which a minority in standing and reputation must yield, if a majority require it,) to hold no brief,—to give no advice,—to furnish no design,—without a competent fee. It is the parties seeking designs, and who desire to derive advantage from the application of many minds to the same subject, that are to be benefited; and they who seek a benefit must be content to pay for it. Moreover, it can never happen, but that in several designs for the same thing there will be some points or parts in some or other of the designs, than that which may be generally the best, better than the same parts in the best design. When all are paid for, all may be used; and the best design in a concurrence may be greatly improved by the incorporation of the excellencies of the others.

Had the course I recommend been pursued in the case of the Houses of Parliament Designs, the eminent architect who was most deservedly successful in that competition must have been included in any number called upon, however limited, because of his already attained eminence, and the country would thus have had the advantage of such improvements in the preferred design as the other concurring designs might have suggested; and this without submitting the architect himself to the insults he received in being charged with pirating un-premiated designs. Reference to this calls to my recollection an instance in connexion with it of the disadvantages architects suffer, from the habit the public, and with the public the public authorities, have acquired of considering architects as mere artists. The architect of the palace of the Legislature was put into leading-strings during the formation of the foundations of his work; and the construction of the river-wall, which forms the effective basement of its main front, was taken entirely out of his hands!

Again, it is essential to the proper understanding of an elaborate design in architecture, that the architect should explain his intentions, with the drawings before them, to the parties who may have the selection. This being done by the four, six or eight architects who may have been called upon,—for where fees are to be paid to all concurring, there would be no advertisement, such as I have often seen, giving permission to, rather than inviting a concurrence of, "*masons, builders, surveyors, and architects!*"—unpractised persons would be able to determine, without great risk of error, upon the design best adapted for what they may want. Favour may determine the selection, certainly, but that is the case now, and to a much greater extent than could be when the more intelligent man was seen in connexion with the better design; and besides this, the uncommissioned competitors would, according to my proposition, be paid for their trouble, and would receive no substantive injury by the wrong the parties might thus do themselves, or those for whom they act, in selecting by favour rather than by merit.

The general competition system has been defended upon the plea that it gives young men opportunities, or chances rather, of obtaining employment that they could not otherwise hope for; but I believe that the moral injury done by the system to young men, in leading them to bow and cringe in seeking favour, and from the unworthy too, and the expenses they may be drawn into, are evils but poorly compensated by the advantages, such as they are. Young men have been ruined for life by success in a general competition; some have been cheated out of the prizes they were declared to have won; and many have been driven to despair by failure, who might in due time have succeeded in obtaining business, had they worked duly, and had they not been tempted out of the beaten path of industry by these *ignes fatui*. Another plea is, that competition designs give architects employment for their pupils. This must, of course, be in the absence of practice; and I introduce this subject here, to take from it the opportunity it affords, of warning students against offices where the usual occupation of pupils is in making speculation designs. You may do such things, if they ought to be done, without paying high premiums for the privilege of doing them in an architect's office.

To make the profession of architecture worthy of a gentleman, you must determine, each man for himself, that it shall be so; and to this effect decline to render professional services in any form, without that species of acknowledgment which it is essential you should obtain, to secure respect for either your services or yourselves.

The Artesian Well at Grenelle.—A new tube is now making for the well of Grenelle in iron, of such a thickness that it will bear the pressure of 50 to 60 atmospheres. Experiments have been tried on two tubes placed one within the other, as the tubes were in the bore of the well, to ascertain what degree of pressure would be necessary to force them in; but though the hydraulic ram was employed, it required a pressure of from 12 to 15 atmospheres to produce any effect on the tubes. The water still flows as copiously as ever, moderately warm, and alternately limpid and black as the sewers of Paris.—*Galignani's Messenger.*

MR. VIGNOLES' LECTURES ON CIVIL ENGINEERING, AT THE LONDON UNIVERSITY COLLEGE.

(Continued from page 60.)

LECTURE VII. Jan. 5, 1842.—The Professor commenced by stating that he had then reached the third division of the first course, and his present lecture would be upon retaining walls. The meaning of the technical terms of "retaining" and "sustaining" walls was—when a wall was used either to support water or earth artificially put together; but when it was used to support natural earth, it was often called a "breast-work." As the term "batir" would often be made use of in that and the following lecture, he proceeded to explain that the batir was the base of a triangle, formed by the slope of the wall and perpendiculars of the other two sides—thus a batiring wall was a sloping wall. The introduction of retaining walls was very ancient; in Italy there were several of great antiquity, formed of concrete, rubble, &c., and even some parts of the great wall of China were built in that way. Retaining walls were generally introduced at the ends of bridges, to connect the abutments of the bridge with the natural ground; but in these cases they were called "wing walls." In forming roads retaining walls were sometimes carried along the sides of the valleys—the road itself having to be cut at times along the sides of hills so precipitous, that half was embankment and half cutting. In the celebrated road formed by Napoleon across the Alps, there were many instances of work of this kind, and good lessons could be learnt from the failures which had taken place, the reasons for which were generally very apparent. In Telford's grand road through Wales, there were many instances of retaining walls, and one in particular, where the road had to pass along the side of a hill which was nearly perpendicular. The great cutting from Camden-town to Euston-square was another instance, but, from certain causes, which he very ably explained, the walls were giving way in many places. He then proceeded to lay down, by numerous diagrams, seven forms of retaining walls made use of, and pointed out, by mathematical formula and practical experiments that had been made, and which the diagrams explained, the best forms for use. In No. 1 the batir was represented as being equal on each side of the wall; in No. 2 the batir was on the side next the earth to be supported; No. 3 was a parallel batiring wall; in No. 4 the batir was next the earth, but at the bottom of the wall, No. 5, the batir was on the outside, at the top; No. 6 was a parallel and perpendicular wall, with no batir on either side; and No. 7 had the batir at the outer side of the wall, and next the earth the slope was cut in steps; these seven diagrams showed the common forms of retaining walls. The grand points to be considered were—1st, the value of the pressure that the earth exercised against retaining walls; and, 2nd, the description and dimension of the wall necessary to offer sufficient resistance to that pressure. It was found that if you take away the wall, the earth will for a short space of time retain its position, but, after exposure, it will begin with crumbling at the edges, and ultimately gain a slope so as to lie at the angle, which is called the "angle of repose." This requires, in building retaining walls, that the angle of repose of the description of earth to be supported should be ascertained; this done, the pressure to be resisted might be calculated, and the dimensions of the wall be decided upon accordingly. Of all the descriptions of retaining walls, No. 3 was the one which offered the most support with the least quantity of material, and which had, by experiments made at Dublin, under the direction of Sir J. Burgoyne and the Board of Public Works of Ireland, been fully proved. The Professor then explained the nature of the several experiments, and the effects upon the walls, exemplifying them by very instructive diagrams. The attention of the students was next called to the curvilinear batir, and several very interesting cases were adduced of failure in that plan, from various causes, but principally from water. He then alluded to two or three failures of his own, and fully explained to the students the causes of them, and the means he should have adopted in the first instance for their prevention. The occasional supporting of walls was judicious in various instances; suppose there was a case, that, while the earth was in an unsettled state, the pressure against the wall was double what it would be when it had settled; in such a case he would recommend supporting walls until the settlement took place—not to go to double the expense for a temporary purpose. He then mentioned a very remarkable instance of an abutment, which was practically a retaining wall, giving way. He had to make an arch of twenty feet span for a river, through an embankment eighty feet high; the foundation was rock, but a sudden lurch took place in the body of the embankment, and the earth forced its way through very many feet of sand backing, drove the abutment or retaining wall clean off the rock, and moved the whole twelve or thirteen feet. Several good rules were then laid down to calculate the description of wall to be used, and method of giving a temporary support until the earth settled; and the learned lecturer, in conclusion, stated that his next lecture would be given on Wormwood Scrubbs, where there were some most remarkable

instances of failures in retaining walls, the reason of which he could better explain on the spot than by diagrams.

THE ATMOSPHERIC RAILWAY.

LECTURE VIII. Jan. 10, 1842.—This being intended as a practical illustration of some interesting and important points, the lecture was delivered on the works of the railways situated at, or near, Wormwood Scrubbs, in place of being given, as usual, in the lecture room of University College.

The first point to which Mr. Vignoles directed the attention of the class was to the atmospheric railway, or rather, a portion of railway laid down on that principle for experimental purposes, upon the line belonging to the West London Railway Company. The length of this experimental line is half a mile, and, according to the Professor's statement, it fully answered the purpose; and he, at some length and with great ingenuity, explained the principles of the system. The iron tube first attracted attention; it is nine inches in diameter, with a grooved slit along the upper surface, which is closed by means of a valve of leather, strengthened by plates of iron, flat on the outside, and forming the segment of a circle on the inside, so as to complete the diameter of the tube when it is shut; at the edge of the valve is a composition of bees'-wax and tallow, which renders the tube air tight. Next was examined the carriage, to which was attached a piston, fitting into the tube, and a very ingenious contrivance was shown, by which the valve was first opened, and afterwards closed down, immediately after the piston had passed, however great the velocity of the carriage. The impossibility of procuring a perfect vacuum had long been assigned as the great objection to this principle of producing locomotion; but Professor Vignoles showed that a good working half vacuum was, by the simple contrivance he had explained, quite attainable, and sufficient for practical purposes. The engine and air-pump were next severally examined and explained, and the lecturer then gave some very interesting explanations of matters connected with the present experimental railway; he stated that the air from the half mile of tube could be extracted in about one minute, while it would take nearly eight minutes for the leakage of the valve and air-tube to admit the air to fill the tube. In consequence of the imperfections in the present line, which had been merely laid down for experiment, the leakage was very much more considerable than when a perfect line should be formed for service; and the formation of a railway on the atmospheric principle would not exceed, perhaps, one-third of the cost of many of the great lines hitherto contracted for, as it would do away with much of the cutting and embankment, the slips of which had recently been so troublesome and dangerous, by the trains being able, on this method, to ascend considerable acclivities. The present experimental line had a rise of about one foot in 110, and he had gone along at the rate of forty-five miles an hour, notwithstanding the imperfections of the machinery and the wretched state of the line. He pointed out that it would be practically impossible for a locomotive to travel upon such a line, as it would be off the rails immediately, in consequence of their being so uneven and loose; yet he had travelled at the rate he before mentioned, with perfect ease and safety, and, furthermore, the extreme simplicity of the machinery rendered it very unlikely to get out of order. A few weeks back the line was required suddenly for some experiment, and, although the tube was half full of ice, in less than half an hour everything was in readiness, and the trial was very satisfactory. The power obtained by the present small tube is 500 lb., with an atmospheric pressure of about 8 lb. per inch only. The engine employed to work the air-pump is sixteen or eighteen horse-power, and the economy of stationary over locomotive power was admitted by every body. He concluded his remarks upon this interesting, and what promises to be most useful application of the power of atmospheric pressure, by detailing, at some length, the minutiae of the saving that would be effected by its general adoption, and stating that two miles were to be laid down upon the Dublin and Kingstown Railway, to try the experiment upon a larger scale, with a tube fifteen inches in diameter, and more perfect apparatus. The Professor then, as the party walked along the line, pointed out to the class various slips that had taken place, some of which were slight and others extensive; one part in particular, situated between the Great Western and London and Birmingham Railways (which are here within a quarter of a mile of each other), attracted general attention, the whole, for nearly 100 yards, being a perfect chaos. A remarkable instance of a failure of a retaining wall here presented itself, it having for about forty-five yards, been actually pushed forward off the foundation, to a distance of eight or ten feet, the wall still standing, which appeared to be about four feet thick, strongly built of brick and concrete, and strengthened with bands of iron and wood. The causes of this destruction were explained by Mr. Vignoles as arising from the lodgment of water, which, having no outlet, had settled the earth against the back of the retaining wall, turning the clay into mud, and, by the great additional weight, forcing it into the position in which it now appears. If the water had been cut off in time this would not have happened, and that water was the occasion of this accident seemed very apparent. The lecturer then pointed out the manner of supporting retaining walls. Several portions of the London and Birmingham and

Great Western Railways were then examined, and much valuable information was given on the various contrivances made use of by these companies, and he concluded by appointing the class to meet on the Croydon and Brighton Railways the next morning, to proceed to the great slip near New Cross.

"THE SLIP" ON THE CROYDON RAILWAY.

LECTURE IX. Jan. 11, 1842.—According to appointment, this Lecture was delivered at the great slip near New Cross, on the Croydon and Brighton Railways. The motive of this visit was to explain to the class the reason of, and to point out the means which might have been taken to have prevented, the great slip which occurred there recently. On leaving the train, the Professor led the way to the spot, which is situated about half a mile from New Cross. The length of the slip is very considerable, the depth of the cutting very great, and the mass of earth that has slipped down from the top of the bank is of an imposing appearance. The appearance of the slip is as usual—perpendicular at the top for some depth, and then bulging out near the centre; a great number of labourers are employed in shifting the immense quantity of earth to be removed, in consequence of the slip, which is estimated at many thousands of yards. In the meantime, a convenient covered walk has been made for the passengers to pass from one train to another. On both sides of this cutting, for some distance along the line, slips have taken place, but on the left-hand side going from London, they are of but little importance, compared with the one that was to be particularly inspected by the class. The soil consists of the plastic clay, with numerous strata of sand and gravel, the clay itself being very binding, but being, from the recurrence of these strata of sand and gravel, very liable to the infiltration of water; and, consequently, to slip, when the up-drainage is not particularly attended to, and the most constant attention paid to every symptom of a slip being about to take place. The Professor then pointed out what he considered to have been the occasion of all the mischief. Nearly all along the slip the earth had given way at the side of a top drain, parallel with the railway, and in some places it was so apparent, that the declivity looked as if made purposely; this had invariably occurred where there were cross drains from the neighbouring ground (which is considerably elevated), leading into the main drain along the top of the cutting, and which, not being puddled, or made watertight, had allowed the water gradually, and during many months, to insinuate itself into the veins in the clay, and had at length forced the mass out as it appeared. He then stated, as his firm opinion, that the slip ought never to have taken place: the earth having stood for three years, was a sufficient proof that the slope was correctly laid out; and, finally, it could only have been by subsequent natural causes that the accident occurred, while, if the precaution of preventing the drainage from the upper fields getting into the body of the slope had been attended to in time, it might have prevented the slip, and it was obvious that the great evil—water—had been gradually insinuating itself into the bank a long time before. In another part of the cutting, he pointed out a place where a slip was expected to take place in the slope; but he disapproved of what had been done by way of precaution, and explained that any operation of making cuts or vertical holes in the slopes, which would admit water, ought to be avoided by all means in the engineer's power, instead of being encouraged. The apertures should be driven in horizontally, and brushwood drains introduced, or a kind of hurdle or *fascines*, which would act as a drain, and be extremely efficacious; on this principle he strongly objected to the cutting of slight surface drains on the slopes, as he thought them worse than useless, being more likely to admit the water than to drain it off. He alluded to a curious circumstance which had occurred a little higher up the line, where the railroad was made in what used to be the bed of the canal. It appeared that there was a spring, and the water, instead of finding its way out of the slopes, actually raised up the rails. Several other points of interest were then examined.

LECTURE X.—Wednesday, the 19th Jan., Professor Vignoles delivered his tenth lecture "On Civil Engineering," on the West London Railway, at Wormwood Scrubs. This was rather a practical illustration, by way of experiment, than a lecture—it being a practical exemplification of the working of the system of locomotion by means of atmospheric pressure, effected by the peculiar valve invented by Messrs. Clegg and Samuda. In addition to the ordinary class, which was fully attended, there was a large assemblage of scientific men, including several of the engineers of the Belgian railways, and officers of the corps of Royal Engineers; Mr. James Pim, and many of the principal proprietors of the Dublin and Kingstown Railway; Col. Jones, Col. Alderson, Major Matson, Mr. Woodhouse, Capt. W. Moorsom, and several other engineers.

SECOND COURSE.

On Wednesday, the 9th Feb., Professor Vignoles delivered his Introductory Lecture to the second course of lectures. He stated that, having in his first course of lectures touched upon several of what he might call the cardinal points of civil engineering, he was then about to enter the second course, for which (according to previously concerted arrangements) one only of the numerous branches of this profession had been selected as the theme, with a

view of entering considerably into its details, rather than to discuss in a more general manner a variety of subjects, which, though perhaps equally important, equally interesting and useful, and equally necessary for the student, could not be thoroughly investigated in the course of a single session. In this introductory lecture he would, however, touch concisely on the wide topic of the internal communications of civilized countries, as falling within the scope of the theories and practice of a civil engineer, treating them here as on a general theme; but the subsequent discourses to the class would consist of the details of that more modern branch of internal communication, of so much interest in the present day—the Railway system. It had been well and truly remarked by an enlightened observer, that the great characteristic feature of the present age was the appreciation of the value of time. In an eloquent introduction to a pamphlet on one branch of internal communication, the author expressed himself in terms which he was tempted to quote, as an appropriate preliminary to his own remarks:—"In that career of improvement which has distinguished the last thirty years beyond, perhaps, any previous history of the world, and in which the sum of the vast ameliorations effected, in all that relates to the condition of man, is not less striking than the rapidity with which their details have followed upon each other; one important lesson seems to have been in an especial degree impressed upon those engaged in the pursuits of industry, and upon the commercial and manufacturing classes in particular—they have been effectually taught to appreciate the value of time, and to apply to its use a degree of rigid and judicious economy, of which the past affords no example; a lesson which is daily illustrated by the vast expenditure, in this country, upon works affording facilities in accelerating intercourse, since it is universally felt that distances are virtually shortened in the precise ratio in which the time occupied in travelling them is abridged." And it is the practical application of this axiom, which it is almost peculiarly the lot of the civil engineer to be called on by the statesman and the capitalist to realise. In looking back through the vista of centuries, and endeavouring to pierce the mist of tradition, we are led to conclude that the formation of roads must have been amongst the earliest rudiments of civilization; but until science, or, at least, until system, was applied to their construction, it is evident (from the traces of the simple paths of comparatively modern times, and of no remote countries) that the merest tracks sufficed to satisfy our ancestors, who had not yet learned the "value of time." Little more was then required than a path upon naturally firm earth—all marshy grounds were avoided—the fords of the rivers were alone resorted to—and the irregularities of surface, or inclination of the road, or its circuitous course, were of little consequence to the pedestrian, or even to the mounted traveller, when man had learned to subdue the horse to his wants and wishes. The path generally traced from one distant wig-wam to another became the track from village to village, and at length served as the road from town to town, or even to the capital. The line once traced out, indolence and habit seem to have prevented any great exertion to improve or repair, beyond what was indispensably necessary, even after the invention of wheeled carriages; and the system of following the ancient course of roads seems to have been pertinaciously adhered to in all countries until the advance of civilization, and the wants of the community, produced improvement, and gave rise to the calling of the road-maker, and ultimately to the profession of the engineer. The first exercise of his art—for it did not reach the dignity of a science until within very modern times—was, probably, in the formation of raised roads, or causeways, to strong holds, dwellings, or cities, accidentally or artificially made liable to inundations; and of this kind were the approaches to the passage of the River of Babylon, which the fables of antiquity magnified into a bridge, as long, and consisting of as many arches, as that in the celebrated vision of the Arabian sage. The first step towards internal communications being roads, it may be well defined as the first step in true civilization, and the Abbé Reynal has justly remarked—"Let us travel over all the countries of the earth, and wherever we shall find no facility of trading from a city to a town, and from a village to a hamlet, we may pronounce the people to be barbarians, and we shall only be deceived respecting the degree of barbarism."

By this test we should probably be induced to judge of the Chinese, if their water communications did not, to a certain extent, supply the absolute want of anything like a road capable of passing a loaded wheeled carriage, even at the gates of Peking. Of all the people in the world, perhaps the Romans took the most pains in forming their roads, and vast was the labour and expense bestowed to make them spacious, firm, solid, and smooth—roads, in fact, from two to even ten or twelve feet thick, formed of what we call in these days "concrete;" but, as regards the system of laying out, in the modern engineering sense, they do not appear to have had the slightest idea. Straightness of direction seems to have been their only character, and, with a lofty disdain of the effects of gravity, their grand military routes, excepting near Rome itself, were carried direct over hill and dale. Thirty roads, of an aggregate length of 50,000 miles, radiated from their magnificent capital, in Italy, to the furthest extremity of their almost boundless empire; they only served as internal communications, for keeping down, by their legions, the rebellious spirits of the Briton, the Hun, the Greek, or the Persian, who had,

in succession, bowed to the Roman yoke—yet, as monuments of the highest degree of art and civilization of those ages, must they be admired by all, and may be usefully studied by the engineer of the present day—few of whose constructions, even the gigantic railway, will probably endure as some of the Roman roads have done—such as the Appian Way, for instance—through the long period of nearly 2,000 years. The number and extent of these roads, made by the first conquerors of Albion, through this island, have only been ascertained and appreciated since the publication of the magnificent maps of the Ordnance Survey by the corps of Royal Engineers, by those who have studied their beautiful and surprising accuracy, and their minute topographical details, which enable a curious inquirer to trace, by their remarkable straightness of course, these ancient routes, through woods and remote districts, and over wide ranges of hills, where their origin, even in tradition, is now forgotten, and where the long lane, grassed over and forsaken, from its steepness or seclusion, accurately laid down, in its true course, by the science of the present day, marks, at intervals, over whole counties, the former line of the stately march of the Roman soldier. But it remains to this day an unsolved problem in engineering, to discover by what means these roads were laid out in such perfect truth of direction, through the thick and trackless forests which then covered the whole island. It has been observed, that it is one of the most difficult points for a political economist to define, with any degree of certainty, the line of demarcation between public and private enterprise, in the execution of works of internal improvement. In a former lecture, he observed that it was undoubtedly owing to the establishment in France, by Richelieu, of the Board of Roads and Bridges, that that country was in possession of excellent roads long before the principal part of Europe; he might have added, also, canals—at least, before we had them in Great Britain, and yet have a good reason to believe that, at the present time, that very establishment is a serious obstacle in retarding the introduction into France of the modern system of improvement of internal communications, by paralyzing the self-dependence of the districts. In this country, the very opposite system, of leaving almost everything to private enterprise and individual exertion, has been most strikingly successful, and has fostered and matured the talent, the ingenuity, the skill, and the experience of the civil engineer, from the competition created by the necessity of individual exertion, which it is presumed would not have been developed, had he been a Government dependant. The origin of the system of forming and repairing roads by trustees, and the collection of tolls for that purpose at turnpike gates, dates somewhat more than a century back, and the rapid improvement of our internal communications, both by land and water, about that time; and it is a remarkable fact, that, when land was of comparatively small value, it was more difficult to obtain ground for a new road than at present, when a square yard of land sometimes costs more than would have purchased a road in former days; and when one of the public objections seriously urged was, that if so many roads and canals were made. It would diminish the quantity of land required for agricultural purposes! But, happily, general knowledge has been diffused, and the former prejudices have yielded to calculation, as man has acquired a knowledge of the value of time, and has found that the payment of turnpike tolls, for good and level roads, is cheaper than to keep extra horses to drag his teams up steep hills, or through marshy ruts. The Professor next stated, that he should not go into the detail, either of the laying out, or the construction of roads, but he must add a few observations, as connected with the duties of an engineer, in regard to some of the general principles. He should accommodate a new line of road to local circumstances, so far as could be without superseding public advantages. It would be ridiculous to follow the old Roman fashion, on the mathematical axiom, that a straight line is the shortest that can be drawn between two points. This would not make the most commodious road—hills must be avoided, towns must be resorted to, and the sudden bends of rivers must be shunned. It is not suggested that roads should be made serpentine, merely for the sake of the picturesque; but the skill of the engineer is to be exerted in avoiding irregularities of ground and irregularity of inclinations, and he will generally find, that a strict adherence to a straight line is of much less consequence than is usually supposed, even in actual distance over long lengths. It was well known that a blind man was, some years ago, advantageously employed through Yorkshire and Derbyshire, in laying out roads through those hilly counties. He followed the streams which made their way amongst the hills, and, by finding out the chords of such arcs, or bends of the river, as passed on practicable ground, he succeeded in his attempts. It is obvious that, when the arc described by a road going over a hill is greater than that described by going round it, the circuit is preferable; but it is not known to the ordinary road surveyor, though it ought to be ingrafted in the mind of the engineering student, that, within certain limits, it would be less laborious to go round the hill, though the circuit be much greater than that which would be made in crossing it. Thus, when a hill has an ascent of no more than one foot in thirty, the thirtieth part of the whole weight of the carriage of the load, and of the horses, must be lifted up, whilst they advance thirty feet. In doing this, one thirtieth part of the whole load continually resists the horses'

draught; and thus, in drawing a waggon of six tons weight, a power to overcome resistance equal to the force of two additional horses must be exerted. But what is here said of level roads must not be strained into an assertion that a perfectly level road is always the best for every description of draught or load. Alternations of rising and level, or of falling ground, are serviceable to horses moving very swiftly; the horse has time to rest his lungs and different muscles, and of this the experienced driver knows how to take advantage; but while this qualification is made, care must be taken not to strain it too much, as did one provincial road maker, who very ingeniously carved a naturally quite level road into a series of short billowy undulations, which his successor had to level again. Without travelling through the whole history of road improvements, he might state that Telford in England and Scotland, and in Ireland, Nimmo, Griffiths, and Edgeworth, brought the laying out and construction of roads to the present perfection; and of the writings of the latter he had availed himself in many of the preceding observations. The many roads of Great Britain were just arrived at almost the highest degree of perfection, when again the increased appreciation of the value of time led speculators to conceive, and our engineers to realize, the idea of the employment of iron surfaces for roads. Before, however, following the gradual transit of roads into railways, he would make a few observations on the other branch of international communication—the navigable river and the canal.

The tastes and speculations of the last fifteen years have been so exclusively devoted to railways as the fashionable mode of internal communication, that canals have almost been lost sight of, and it is now nearly forgotten by the modern speculator, though it may be interesting to the young engineer to be informed, that fifty years ago the mania for constructing canals and improving river navigation was as great, even if not greater, than the enthusiasm displayed very recently about railways. Parliament was then deluged with applications to grant Acts of Incorporation for canal companies; the press teemed with canal publications, the shop windows were filled with canal maps and sections, and the papers and periodicals with advertisements and paragraphs on canalization. Canals appear to have been duly appreciated in ancient times, and used for the purpose of drainage, irrigation, supply of water, and navigation. In his former introductory lecture he alluded to the canal of Xerxes, at the foot of Mount Athos—an attempt which is stated to have been renewed by the Roman emperors in later ages. A canal navigable for large boats was constructed by the Ptolemies between the Nile and the Red Sea, though it is doubtful whether the state of engineering skill in those days permitted an actual junction to be made: this grand navigation was re-opened by the caliphs in the seventh century. Traces of it are still existing, and its termination in the most easterly branch of the Nile was discovered by M. Boutier, in 1707, and is still open. Under the enterprise of the present ruler of Egypt it may yet fall to the lot of an English engineer to re-open this magnificent canal. Herodotus assures us that the Nile was in itself, or by lateral canals, navigable by the ancient Egyptians for 500 miles above Alexandria, and the Delta of the Nile was formerly like modern Holland, filled with canals. The Romans made more than one canal in England; the most remarkable was that called the Caerdyke, which united the river Nene, a little below Peterborough, with the river Witham, three miles below Tiverton; it was forty miles long, and fifty years since appeared distinct enough, and must have been originally very deep; and what led to the impression that this canal was used for the purpose of internal communication, was that there was a continuation of this canal from Lincoln to the Trent above Gainsborough by the Foss Dyke, which is at the present time a fine navigable canal, though, in former times, it had been repeatedly filled up and gone into disuse. It is believed, on good authority, that by these two canals the favourite colony of the Romans at York received their chief supplies of grain. The canals of China have always excited great interest since the description given of them by the Jesuit missionaries; their accounts, as far as regards the Great Canal running from north to south (connecting, except at one short portage, Canton and Peking), have been completely confirmed by modern travellers, particularly by Barrow, who travelled the whole length. Should the existence of the numerous lateral and other canals over the rest of the country be confirmed, of which there is little reason to doubt, it will sufficiently explain the non-existence of anything like good roads, and the almost total absence of wheeled carriages for goods, to which the diminutive and bad breed of horses in China, no doubt, contributes. There is, however, a wide field opening in that country for the exercise of the skill of an enterprising engineer, since that ingenious people are as yet ignorant of the modern lock for their canals, and when two canals meet, the difference of the level is sometimes from fifteen to twenty feet, and the boats are hoisted from the lower canal up an inclined plane of smooth masonry by capstans, and slide down another into the upper canal. The professor stated it would lead him too far to go much into the history of canals, but he must allude to the great canals and inland water communication of the Mogul country, in the East Indies, made by the Emperors 500 or 600 years since, for which the natural features and vast rivers of Hindostan afforded great facilities, and

rendered lockage unnecessary, and, indeed, roads were unknown, and may be considered as still wanting all over India, excepting our recent military roads. This country presents a vast field for the civil engineer. Of all the canals of modern Europe he would only notice two remarkable instances; J. Perry, an English civil engineer, was employed by Peter the Great in the beginning of the last century to design and execute several canals, in which the German military engineer (Brockel) who had attempted them, had entirely failed; Perry's designs were subsequently completed by Peter's successors. The canal of Trolhatta, in Sweden, the difficulties of which had long baffled the engineers of that country, was finally completed by the skill of the late Mr. Telford, whose engineering resources were equally displayed in the design and execution of the Caledonian Canal. Many remarkable instances of success in making an imperfect river into a good navigable stream might be quoted both in Europe and North America, and which present instructive instances to the young engineer. The improvement of the river Liffey at Dublin, and the River Clyde in Scotland are good examples. The improvement of that vast inland gulf, the Shannon, is now in the course of execution, after several years of most detailed and elaborate inquiries, estimates, surveys, and careful examination, the accounts of which may be studied with great advantage to both the experienced and young engineer. Upwards of half a million sterling is to be expended on this truly national undertaking. The learned professor then entered into a long account of the probable original ideas for the application of iron to roads, commencing with the wooden railways used in the collieries on the banks of the Tyne, near Newcastle, above 200 years ago, he then showed that the waste of timber led to the idea of covering wood with plates of iron, and ultimately to the present point of perfection—wrought iron rails—the introduction of which into general use does not extend further back than thirty years.

(To be continued.)

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

Jan. 31.—P. HARDWICK, Esq. in the Chair.

A paper by Mr. White was read on Fresco Painting, which will be found in another part of the Journal.

A paper "On the Vaults of the Norwich Cloisters," by Prof. Willis, of Cambridge, (hon. member,) was read. The following is an abstract:—

The cloisters of Norwich Cathedral were begun in 1297, and not completed until 1430. Its four ambulatories represent four successive styles, the contrast in the details being rendered more conspicuous by the uniformity of the general design, which has been so much respected during the progress of the whole work, that even the isolated shafts, which form the proper mullions of the windows of the thirteenth century, have been continued throughout, contrary to the usual practice of the Middle Ages. The vaultings are similar in the general plan and dimensions on the four sides, but each is distinctly marked with the mode of treatment employed in the successive periods, and it is to the progressive variations in the form of the spandril, exhibiting a gradual transition from a square section to a semicircular one, that the paper chiefly referred. In the oldest portion of the work, the eastern compartments, the horizontal section of the spandril, taken about half way between the plane of the impost and the crown of the arch, is perfectly square, and this form is more strongly developed—exaggerated, it may be said—by a slight setting back of the ribs between the cross springers and the diagonals, which gives greater prominence and a more marked expression to the angle of the spandril. In the south walk, the next in chronological order, the intermediate ribs, instead of being set back, are brought slightly in advance of the other ribs. The effect of this arrangement is to give a polygonal character to the spandril, which is, in fact, still square in its general form. In the west walk, the polygonal character is fully developed, and the square abandoned, but the angles of the polygon are far from being equal. In the western walk, the latest portion of the work, four centred arches are introduced, and the curves of the haunches being all alike, and the middle section of the spandril circular, the polygon formed by the front edges of the ribs is equiangular, as in fan vaulting. These effects, continued the Professor, may be confirmed by the comparison of contemporary examples, but it rarely happens that they can be found in a series, and in a work of which the uniformity of design is for the most part preserved; so that changes of this kind are rather to be regarded in the light of embellishment, or as the modern improvements of the day added to the original design. Thus it is, that in this respect the cloister of Norwich is so valuable, by enabling us to discover many of those improvements which it is more difficult to pick out of examples complete in the character of their own age. The essay was accompanied by numerous sections, and a table laying down the exact curvature and arrangement of the vaults: all the curves are found, in conformity with all that has hitherto been observed on the vaultings of the Middle Ages, to be segments of circles, and not ellipses formed by projection, according to modern practice, which has, therefore, erred widely in the character of Gothic vaulting.

This paper forms a sequel to that on the Vaulting of the Middle Ages in general, read by Prof. Willis, at the Institute, on the 5th of July, 1841. (See Journal for Aug. 1841.)

Feb. 14.—JOSEPH KAY, Esq. V.P. in the Chair.

This evening was one of more than ordinary interest, in consequence of its having been announced that the long-desired wish of many members of both the Institute and the Architectural Society for the union of the two bodies would take place. There was a very full attendance, so much so that the room was crowded to inconvenience. The preliminary arrangements having been completed, 32 members and students of the Architectural Society were admitted, 11 as fellows, 8 as associates, and 13 as students of the Institute. The Architectural Society will, therefore, be extinct after a final *conversazione*, to be held at their rooms in Lincoln's Inn Fields, on the first instant. This union, we consider, will lead to very beneficial effects, and will give a firmer basis to the profession; so that we hope now that attention will be seriously turned towards remedying the evils respecting "Competition Designs," so long complained of.

ON FRESCO PAINTING.

A Paper read at the Royal Institute of British Architects, by E. T. PARRIS, Esq., on Monday, 14th Feb., 1842.

THE application of the higher branches of painting to architectural decoration, is a subject in which the members and gentlemen connected with this Institute have taken so much interest, that I need only refer you to the many valuable papers which have been read before these meetings on the art of polychromy, the works in the Vatican, and others relating to painting, all tending to prove that such embellishments are considered by the profession as essential to architecture.

The liberality of the council, by their invitations, show the earnest desire on their part to promote the permanent union of architecture, sculpture, and painting, and is, I am sure, fully appreciated by my brother artists, and every visitor present, as well as myself.

I have, therefore, endeavoured to collect together a few remarks founded on my own practice, in the hope they may assist in restoring that confidence so essential on both sides in carrying out great works.

It will be remembered that in 1821 a new ball and cross was placed on the summit of St. Paul's Cathedral; and as the interior was intended to be cleaned, the question was much agitated respecting the paintings in the dome, by Sir James Thornhill. It was stated publicly that the expense of raising a scaffolding would be so great that faint hopes were entertained of its being effected; I immediately turned my attention to the subject, and contrived an apparatus for the purpose of getting at the paintings. The model remained by me until 1829, when Mr. R. Cockerell, desirous of seeing the paintings cleaned and restored, submitted the model, in the most liberal manner, to the Dean and Chapter, introducing me at the same time as the inventor; the apparatus was considered adequate to the purpose, and my estimate for restoring the whole of the painting, gilding, &c. above the whispering gallery was £1000, and no charge for scaffolding! but this sum was too large, and the plaster has been dropping from the wall ever since—(it had then decayed above five feet all round the dome)—and I am certain that in a few years the whole of the brick work will be exposed. What could H. M. the King of Prussia think on entering our metropolitan cathedral? It may be readily imagined that the hope of employment on such a work, excited the liveliest enthusiasm, and I lost no opportunity of devoting every spare moment to experiments on stuccos and cements, as I fully expected on touching the plaster the greater portion would come down; my intention was, in that case, to propose the restoration and painting to be done in fresco, it having been originally painted in oil. Perhaps there are many gentlemen present who visited Rome from 1820 to 1825, and they will remember that Cornelius, Overbeck, Veith, &c., then were employed by Chev. Bartholdy to paint his villa in fresco. The attempt to revive this method of painting was considered an experiment, and the English patrons and artists looked on, talked about it, but did nothing; one gentleman, an architect and member of this Institute, in the most laudable manner tried to engraft it in this country, and had a large surface covered for that purpose in the Catholic Chapel in Moorfields.

The result of my experiments at that time, with much practice on large works since, together with the attention I have recently given to this subject, emboldens me thus to lay before you the following observations. I shall first endeavour to explain the different ways of using colours in painting, and offer my opinion as to the best appropriation of each to its particular

purpose, and although fully aware that practical men, and experienced architects are acquainted with their qualities, yet there are many who, practising one mode of painting, are ignorant of all the others, particularly as applied to architectural decoration.

The covering large surfaces, and the representation of subjects and ornaments by colour, is performed in either what is called fresco, distemper, encaustic, or oil (with varnish or without) termed *fatting*.

Oil painting consists in using pigments mixed with oils, gums, or other vehicles, for the transparent colours, and with opaque bodies, such as white lead, and metallic oxides, for the lights; the extensive range or scale from light to dark, through all the varieties of colour, from the most delicate tint to the most juicy richness, gives it many advantages for general purposes, which no other mode possesses; the ease with which it is worked, the numerous re-touchings, toning, scumbling, glazing, &c., renders it a most fascinating medium to convey the ideas of the artist to the canvas, panel, or wall. Durability is another of its advantages; and it would appear to possess every requisite for embellishing the ladies' boudoir, the picture gallery, or public edifices of the greatest magnitude, or most severe character. But upon mature reflection it will be seen, notwithstanding the extensive powers of oil painting, that it is used to the best advantage when applied to certain sizes and positions, and when confined within panelling or framing, and so placed as to receive the light from a particular angle, as its glossy surface reflects all objects before it. The ceiling by Rubens at Whitehall will explain this, for since it was last cleaned, the canvases of the centre oval appears quilted, in consequence of the cord which suspend it rendering the surface uneven, and it can only be seen from a very few parts of the chapel without those shining little spots. The same cause operates upon oil painting, when applied to staircases, cooves, and curved surfaces, and the staircase and saloon at the British Museum, the hall at Greenwich Hospital, and other places, are examples of its misapplication. It may be stated in answer to this, that there are many paintings on a large scale which do not shine; this must be allowed, but the cause is that they have, from age, &c., become mealy and dry in their shadows, losing all their transparency and richness, and in many cases the dark colours are covered with a grey cloud, and the usual cry is—How much they want varnish.

I am also aware of the various methods used to destroy the gloss of oil pictures when placed opposite to windows, as starch, rice, white of egg, and spirits, with several others; but in every case that I have seen and tried, the richness of the deep colours and shadows are reduced to the dullness of distemper; the excessive blackness in the staircase at the British Museum, &c., is occasioned by the boiled oil used in preparing the grounds to prevent damp from coming through; this never occurs in pictures painted with pure oil. Many attempts have also been made to unite the qualities of fresco, encaustic, and distemper with oil, by using one over the other.

Painting in distemper, or body colour, is so inferior to oil, that few artists in this country practise it for pictures, although much used in Italy. Yet it has some important qualities which fit it for purposes wherein oil would fail; it is a mixture of colours, with whiting and size, gum, white of egg, or other glutinous substances, it cannot be softened or blended without great difficulty, so that in most cases, where finish is required, the several tints are carried into each other by hatching with the point of a hair pencil, as in the Cartoons of Raffaele at Hampton Court. Its extraordinary power of reflecting light equally, renders it best adapted for scenery and gay light decoration. Its chief characteristics are, that it represents air, distant landscape, architectural objects and sculpture, better than by any other means (when on a very large scale, and the spectator is kept at a distance), for on approaching it appears dry and unfinished. Its chief objection for architectural decoration is, that it suffers from damp, and is removable with a sponge and water. Most colours can be used in distemper, even some that are useless in oil, as verditer and others; all the bright and rosy tints are seen to the best advantage when used in distemper.

Painting in turpentine, or as it is termed *fatting* or *dead colour*, is a modification of oil painting, no varnishes being used but turpentine alone (excepting the oil in which the colours have been ground). Its qualities are very similar to distemper, with the advantages that the colours may be blended and softened into each other; but dispatch and rapidity of execution is necessary, or the painting will shine in those parts where the brush has passed frequently over. It represents air and distant landscape equal to distemper, and may be carried to the extreme delicacy of finish; but on a very large scale, it loses its force in the shadows, reflects considerably less light, and appears weak in comparison with distemper, it is as durable as oil would be without varnish.

As to encaustic painting, I must confess my inability to explain its best qualities, or do it justice, the few experiments I have made and seen not being sufficient. Its general principles, however, consist in a mixture of gum mastic, wax, and gum arabic, boiled in water, and used with powder colours on dry plaster, canvass, or panel, after which a coat of melted wax is spread over the whole, and a hot iron applied to drive the wax into the painting, and to incorporate with the colours, by which they are rendered more transparent and bright. Another way is to prepare a ground of wax, paint upon it with distemper colours, and when dry apply hot irons, and it will be fixed.

In all my experiments, I never have been able to remove a cloudy appearance, or to drive in the wax equally, when on a surface of any size; but I believe the recent discoveries of the French artists have brought it to maturity. It was much tried a few years ago, and I have seen several pictures which were thought successful, but they never exceeded eighteen inches square, and had a semi-transparent appearance (from the wax) like marble; they must be very permanent, and resist the damps of a moist climate. Durability without gloss is its chief advantage, it can be retouched and painted upon at any time, so that careful cartoons, and a thorough knowledge of drawing are not so essential as in fresco.

Fresco, a term not generally understood, was greatly talked about 20 years ago, and at last has become a question of national importance. It was supposed a secret and mysterious operation, whereas of all other modes of painting it is the most simple; I am therefore astonished that many writers upon it, and some of them artists, should bring forward such opposite opinions, when a single experiment would prove the permanency of the colours, and explain the whole affair.

From numerous experiments I have made, I believe that all our usual mortars will answer equally well, as far as the operation of applying the colours. The durability of the stucco is another consideration; the practical plasterer will know what mixtures work the best, and the experienced architect can inform us of the materials to endure the tests of time and climate.

I think it not likely the Greek artists used exactly the same composition for their stuccos in their own country, as they did at Pompeii and Herculaneum, or that Masaccio, Michael Angelo, or the Sicilian artists, painted on a preparation, precisely the same as those now practising at Munich, and I am convinced that the painter will find walls, and stuccos, ready prepared to his hands for fresco, as good as he can desire, either in England, Russia, India, or America.

The process consists in laying and spreading very even, a mortar composed of lime mixed with either sand, pulverized flint, bricks, or glass, and while it is fresh and moist, to apply colours prepared from earths and minerals, mixing them with water, the whole will become chemically incorporated and fixed when the stucco is dry, and will become so hard by time as to bear rubbing with a wet sponge or cloth. It must be remembered that vegetable colours will not stand. Those to be used in fresco painting are few, of a deep sober tone, of great intensity, and are very brilliant when judiciously contrasted. In this the knowledge of the artist is called forth, as in every other method of painting, and a very little practice will teach him the few changes which take place in the drying of his tints. Although small works of the greatest excellence have been executed, and by the first masters, yet the proper field for fresco is in figure subjects on extended surfaces, and it is most effective when in conjunction with sculpture and architecture.

As a decoration, it surpasses every other mode of painting; its grand and impressive tone of colour, with a boldness and decision of outline rejecting all meretricious ornament, and its combining with large masses of architecture, give a dignity and majesty commanding silence and admiration.

I must observe that much of the richness and brilliancy of fresco, depends on the stucco ground reflecting light through the colours, and Indian red, when applied on a large surface, appears as beautiful as the richest lake in oil. The colours never grow darker, nor do they suffer from absence of light. Their durability is beyond a doubt.

A very general impression exists, that any painting done on a wall is fresco. This is a mistake, as none of the works by Thornhill, Verrio, and others, are in fresco but in oil; also that the scenery at the theatres is fresco; they are not so, but in distemper. In fact nothing can properly be called fresco that is touched after the fresh mortar is dry and it is moreover supposed that the English artists are entirely ignorant of this mode of painting. This again is not true; many have tried and succeeded; and there is an interesting account in the "Art Union," of last year, describing a work by Thomas Barker of Bath, thirty feet long, and twelve high, full of figures

the size of nature, painted in 1822, about the time that the German artists, commenced fresco painting.

Fresco painting, ancient stained glass, objects in terra cotta, bronzes, tessellated pavements, with painted and gilt monumental effigies, armour, and old tapestries, seem to partake of the same qualities, that of a sober, powerful, rich, and if I may so use the expression, a ponderous character, which accords not only with each of these, but with every style of architecture.

In opposition to this painting in distemper, turpentine and oil require to be modified or humoured to suit the exact tone of the apartment; the Venetian artists well knew this, and their oil pictures were frequently painted very rich and dark, to harmonize with coloured marbles, velvets, brocades, embroidery, and carved ebony, with which they were surrounded, but as form and outline were absorbed in those powerful effects the higher style of art became disregarded.

Enough was done by Rubens to show the value of painting as an architectural decoration; and although the possession of the cartoons produced no commissions for our native artists, yet the nobles engaged Verrio, Rizzi, Pellegrini, Rousseau, Delafosse, and others, to cover the walls and ceilings with their preposterous deities in silks and satins, powder and perriwigs.

Thornhill, an Englishman, endeavoured single handed to form a school for his country, which was encouraged while he lived. It is however stated by his son-in-law Hogarth, "that the upper end of the hall at Greenwich, where the royal family is painted, was left chiefly to the pencil of M. Andrea, a foreigner, after the payment originally agreed upon for the work was so much reduced as made it not worth Sir James' while to finish the whole with his masterly hand."

It is curious to note the scale of charges for architectural decoration for the last 200 years. That is from the arrival of Rubens in 1630 to 1730, when Thornhill was in his zenith; and from 1730 to its almost total extinction in 1842.

1630 Rubens, for Whitehall ceiling	£ 7 10 per yard
1670 De la Fosse, British Museum	7 0 "
1690 Verrio, exclusive of gilding (with 200 <i>l.</i> per annum when blind)	3 12 "
1725 Thornhill for Greenwich	3 0 "
1730 Do. pilasters	1 0 "
1775 Cipriani for cleaning the Rubens ceiling, £2000.	
1777 Barry for the paintings in the rooms of the Society of arts, after being furnished with colours received by the exhibition, £503. 2 <i>s.</i>	

The practice of fresco painting will be found to produce strong sensations both in the artist and the public; and they will discover hidden beauties at present scarcely known to exist; it will draw the attention of the painter to works of art hitherto glanced at as being out of his style—the Elgin marbles will become properly appreciated, he will disseminate the admiration to his pupils, and through them the public will have their eyes opened to the riches they possess in those inestimable treasures of art.

It is objected that fresco painting cannot be removed like oil. I beg to refer to those painted by Paul Veronese, and brought to this country a few years since. It may be done on slate. I do not insist that fresco is either better than oil or encaustic, or that it is more effective, except for particular purposes, but it has advantages over every other style; it can be done in less time for less cost, and produce a larger income to the artist; is certain of raising the arts as well as the taste of the manufactures, consequently must increase the revenue of the country.

In fresco painting, the artist requires numerous assistants, and some of his own creating; they must be his pupils, with them he receives premiums for instruction; he has also the benefit of their aid, and is therefore not obliged to devote so much of his own manual labour to express his thoughts; and when he commences his work upon the wall it is soon dispatched, while the scaffold is up and the wall damp, without waiting for its drying, and then four coats of oil, and a flat before he begins.

The ability of our artists in drawing is part of the great question; it will be seen and more fairly decided when the sketches of foreign artists are placed beside them, if they will come forward by the general invitation to artists of every nation; if they do not, they are not entitled to be employed. Models for sculpture should be limited in size, and decided upon after three months public exhibition.

After the first selection is made, the artist and architect would be "working in conjunction and in aid of each other," as desired by the select committee; each would appreciate the talents of the other as they became developed, and the architect would be saved the mortification of having his

edifice encumbered by a mixture of German saints, Greek and Roman heroes, and paintings of Turkish battles, all perhaps good in themselves, but destructive to his design from their wrong application.

It would be necessary for the architect to have proper scaffolding, and other conveniences as the decorations would then really form part of his undertakings and estimate.

I must now leave this and all other remarks to your consideration, and sincerely trust that what I have stated will be understood as not intended to draw forth opinions, but experiments. I have endeavoured to explain the results of mine, and if I have made erroneous conclusions, I am sure that no one will more gladly be undeceived when proofs are given to the contrary, and I trust we shall be able of ourselves, not only to embellish the Houses of Parliament, but all other public edifices, without foreign aid, both in oil, encaustic, and fresco.

REVIEWS.

Papers on subjects connected with the Duties of the Corps of Royal Engineers. London; John Weale, 1842.

WE have before us the fifth volume of papers by the Royal Engineers, one of increased size; and we have not yet seen the third volume of the Transactions of the Institution of Civil Engineers, although upwards of two years have expired since the second volume appeared. It was, in fact, in Nov. 1838, when that volume was produced; and as the first volume of papers by each body was commenced at the same time, there must, in our opinion, have been great remissness on the part of the Institution, in allowing their military brethren to get so much ahead. Want of papers can be no plea in excuse for this delay, for there are plenty of them read at the meetings, many of which, well worthy of publication, are doomed to seclusion in the portfolios of the society. We shall not, therefore, witness the continuance of this state of affairs, without feeling it our duty to comment upon it more strongly.

When it is considered that the interest of the papers is enhanced by their speedy publication, we cannot but regard this delay as most injurious both to the progress of science and the interests of the profession. The civil engineer and the royal engineer will both be judged by their deeds; and if the latter succeed in bringing forth three volumes to one, they will naturally become more familiar to the public, and in the end perhaps supplant the civil engineers in all government works, an enterprise which will but too well meet the encouragement of the ruling powers. When it is further considered that the royal engineers are united on this occasion merely by a private compact, and that the civil engineers form an incorporated body, we think it becomes the bounden duty of the Institution to be more zealous in their exertions, and more liberal in their measures. It is their duty to promote science, and to diffuse information; for the more the public becomes enlightened as to the powers of the engineers, the more will they be disposed to encourage public works.

Having said thus much, we shall proceed to examine the contents of the volume before us, of which the first two papers are purely military. The third paper is on the removal of a wreck; and the next paper on the Madras Lighthouse, and the mode of its illumination. The fifth paper, by Lieut. Nelson, R.E., treats of the varieties of timber, and has tables of their degrees of strength. Many of the specimens are of woods upon which hitherto no report has been made. We regret to observe, as we have on previous occasions of this kind, that the experiments were not made on larger scantlings; nevertheless the paper appears to be got up with care, and to be more copious than any we have yet seen. The next paper is on the canal navigation of the Canadas, by Lt. Col. Philpotts, illustrated with maps and a plan, sections, and details of one of the locks. The seventh is a description of a traversing crane of considerable strength, used by the Butterley company, well adapted for raising great weights, communicated by Mr. Joseph Glynn. The eighth is an interesting paper by Major Jones, R.E., on the method of building in Malta. The next paper, on drawbridges, is a valuable communication from Lieut. Douglas Garton, R.E., chiefly derived from the French of M. Poncelet. It is illustrated with three plates, containing several varieties of this kind of bridge. The tenth paper illustrates, in much detail, Mr. Napier's machinery for the manufacture of leaden bullets by compression, by which 25,000 bullets can be produced in a day. In the next paper the editor describes the new dock constructed at Woolwich under his

superintendence, in conjunction with Mr. James Walker. Mr. Miles, in the twelfth paper, gives an elaborate account of Huddart's rope machinery used in Deptford dock-yard, whose patent has now expired. It is accompanied by seventeen beautiful engravings by Le Keux, drawn with great accuracy, and exhibiting all the details. To persons who feel an interest in this subject, we recommend this article for perusal. The next paper is on the theory and practice of sinking Artesian wells, including one at the model prison, Caledonian Road, Islington, which is the deepest yet sunk in the chalk of the London basin and shows the abundance of water to be obtained from that stratum.

It will be seen, from the list of papers which we have given, and from the extent of illustration, how much the editor has exerted himself for the improvement of his work. We hope hereafter to make some extracts from this work, to which we have not now space to do justice.

Remarks on English Churches, on the expediency of rendering Sepulchral Memorials subservient to pious and Christian uses. By J. M. MARKLAND, F.R.S. & S.A. Oxford: Parker, 1842.

MR. MARKLAND'S book is rather addressed to the public than to architects; but it will render essential service, by directing men's views to the many considerations connected with ecclesiastical architecture. To preserve the works of our ancestors from decay, and to protect them from the injuries inflicted by barbarism—to add our share to the accumulated architectural wealth of ages—are obligations which cannot be too generally enforced, and which are well urged by our author. His work is one of a numerous class which we see issuing from the Oxford press, betokening the increased interest of the clergy in ecclesiastical architecture, a feature which we are glad to recognize, as the clergy have mainly assisted in the decline of that art, and are the parties who can most efficaciously co-operate in its restoration.

The Year Book of Facts in Science and Art. By the Editor of "The Arcana of Science." London: Tilt and Bogue, 1842.

THE numerous facts contained in this yearly volume afford a complete index to what has been done during the past year in the arts and sciences; it is a book full of useful information collected from several periodicals, and shows the industry of the editor in stringing together so much valuable matter.

Telegraphic Railways, or the Single Way recommended by Safety and Economy. By WILLIAM FOTHERGILL COOKE, Esq. London: Simpkin Marshall, and Co., 1842.

MR. COOKE, the co-patentee of Professor Wheatstone in the electric telegraph, has written this small volume to illustrate its working, and to show the economical advantage which may be derived from its employment. The author shows clearly that in the majority of cases, the application of this apparatus will enable companies to work a single line with safety, and so to avoid the great and heavy expense of double ways, so unsuitable for a restricted traffic. This is done with impartiality, although an inventor is speaking of his darling project. Mr. Cooke has made out a very strong case, which we think highly calls for the enquiry of the railway proprietor and engineer.

Illustrations of the Architecture of Nicholas Goldman. By H. AUSTEN, Architect, Liverpool. London: Green, 1841.

MR. AUSTEN'S re-publication of Goldman's work is too expensive for students, and the illustrations badly executed; nor is the small quantity of letter-press carefully edited.

ON INCREASING THE EVAPORATIVE POWER OF BOILERS.

SIR—Perceiving in your last Journal a review of my suggestions for increasing the evaporative power of boilers, and also for preventing the nuisance from smoke, in which the writer has indulged more in wit than argument, I beg, while passing over the former, to reply to that portion of his review which bears on the above important subject, and, at the same time, is more in harmony with the scientific nature of your useful work. The reviewer has indulged in much personal matter, and even personal abuse; but as I have not leisure to comment on such, and am persuaded you would object to have your valuable columns so occupied, I will confine myself to the scientific and practical, leaving the figurative and redundant matter to the neglect which is perhaps its best reward.

After a long quotation from the *Mechanic's Magazine*, (No. 950,) giving the substance of a communication made by me to a highly intellectual and practical auditory at the Polytechnic Society of this town, in which I explained a mode of increasing the evaporative power of boilers, by the transmission of heat, *longitudinally*, through metallic bodies, (and the whole of which quotation I assert to be substantially correct,) the reviewer observes, "Well: if this be not carrying absurdity to an imperial pitch, we do not know what is." Now Sir, I can only say that this "imperial absurdity" has yet to be pointed out; for assuredly none of my auditory were able to detect it, during their examination of the experimental boilers then in action before them, and after an interesting discussion to which it led. I may also observe, that after I had concluded, Mr. Dewrance, the engineer of the Manchester and Liverpool Railway, stated to the meeting that he had inserted 105 such conductor pins into one of the company's stationary engine boilers, and that it was attended with so decided an effect, that the boiler now produced an abundance of steam, although previously its supply was very deficient.

Yet what is this "absurdity," of which the reviewer speaks? Neither more nor less than the practical application of the well-known theory of "conduction," which may be found in every work of authority, treating on heat, and its transmission through metals. The application of this heat-conducting power of metals, of which I avail myself, is by introducing metallic pins projecting a given length into the flues of boilers, and by which a greater quantity of heat will be conducted to the water than would be due to the area which the pins displaced. On this head, the reviewer quotes the words I used, viz. "The half-inch circular portion of the flue-plate which such pin has displaced, is thus made to possess the faculty of transmitting as much heat as is received and absorbed by nine half inches superficial" (the pin being half an inch in diameter and three inches long). Now this statement, I repeat, is strictly true, in defiance of the reviewer's charge of "absurdity." The reviewer, however, putting his own erroneous interpretation on these words, raises an imaginary superstructure, which he attacks with genuine Quixotic ardor, and equally Quixotic effect, for he adds, "by which we understand that the pin has the effect of transmitting to the water nine times as much heat as the half-inch disc it displaces." Now this is a mere gratuitous misunderstanding of a very plain position. I did not give any measure or quantity of heat, so transmitted; I merely said, "as much heat as is received and absorbed;" for on this very distinction depends the whole question, inasmuch as it is an ever-varying quantity, and influenced by numerous physical and accidental circumstances, such as, the length and thickness of the pin—the nature of the recipient—the part of the plate in which it is inserted—the quantity of soot or other non-conducting matter with which the flue may be lined—the strength of the draught or current through the flues—and the temperature of such current.

Nowhere, however, will he find me committing the practical error, which he puts into my mouth, of measuring the quantity of heat transferred, by reference to the mere surface area of the pin, spike, bar, or plate. Indeed, had the reviewer examined impartially and quoted fairly, he would have found in the very report from which he quotes, (see *Mechanic's Mag.*, No. 951,) that such is the reverse of what I inferred; for I there stated that three-inch pins were practically the best, repudiating the idea of increase of surface being commensurate with increase of heat.

Whether the area of the disc of the plate displaced will transmit heat in proportion to the surface of the conductor pin, will depend much on its length and other circumstances. I am prepared, however, to prove that a pin half an inch in diameter and three inches long, inserted into the side of a flue plate, will absolutely convey more heat than nine half inches of the plate surface, although I do not assert the

same thing of other lengths. Besides, there is another consideration which requires attention, namely, the distance of these pins from each other; since, were they too close, they would counteract the object intended, and prevent access of the mass of moving heating gases to their sides or surfaces. Indeed, in certain parts of the flues, particularly of marine boilers, I believe the heat transmitted will considerably exceed the above proportion of nine to one, a point which hereafter will be practically illustrated.

Of the transmitting power of a metallic conductor, if the reviewer will consult "Brande's Manual of Chemistry," (2nd ed. p. 155,) he will there find the doctrine explained, and a diagram, representing the very experiment, as I saw it illustrated by Professor Brande himself, in his Lectures at the Royal Institution, and which first suggested to me the idea that longitudinal conduction by metallic pins was available for increasing the effective heating surfaces of boilers; and on this ground, that the receiving or heat-absorbing surfaces were large, and the discharging or conveying areas were small—a circumstance which so admirably fell in with the restricted conditions of marine boilers. To this also, I soon found that in practice the system of *longitudinal* conduction had another important feature, namely, that it extended or projected the receiving surfaces, beyond the mere surface of the plate through which the pin passed, and which too often was covered by a coat of non-conducting soot; and further, that the pins presented themselves to the direct action of the current of heated gases, whereas the plates themselves lay in the same direction and plane of the current, and therefore receive but indirectly, and in a less degree, the heat of such current.

Practice has since fully established the correctness of Mr. Brande's illustrations, and the inferences which I drew therefrom; and I can assure the reviewer, that although there were above 1000 persons present, none ventured to call the theory an "absurdity," or imagine that he meant to say that the heat transmitted was in the ratio of the surface and sectional area of the bar he employed.

The mistake, however, into which the reviewer has fallen, and in the enjoyment of which he revels, has arisen from his overlooking the fact, that this conducting power of a given length of bar, though true to a certain extent, is nevertheless not infinite; and that the mere amount of surface is not to be taken as the measure of the heat transferred. This I have sufficiently explained; the reviewer, however, led away, no doubt, by the heat of his own imagination, has taken the length of the bar and the stretch of his own fancy as equal measures of inferential absurdity.

The reviewer observes, "These spikes will, of course, speedily attain the temperature of those particular parts of the flue where they are inserted." This, I take leave to say, is another of the practical errors into which his fancy (or, perhaps, a foregone conclusion that Mr. Williams must be proved to be wrong) has led him. If this doctrine were true, then we should find the plates also of a boiler attaining the temperature of the flues adjoining, which would at once negative any conducting power. So far, however, from these spikes attaining such high temperature, practice proves, that so long as water is the recipient of the heat they convey, the temperature is, in fact, so low as to be touched without inconvenience, the heat passing through them as fast as it is received, thus preventing such an accumulation of heat as would injure or effect their structure; such, indeed, is the well-known cause of the material of all boilers remaining uninjured, although exposed to very intense heats. I here beg to refer to a paper and diagram in the *Mechanic's Magazine*, No. 967, in which I have gone more at large into this important subject.

I here pass over the strange train of reasoning which the reviewer indulges in, and the equally strange hypothesis he broaches, manifestly from the mistake above noticed; namely, that "a single spike will be as efficacious as any given number of spikes, provided it have a commensurate surface," and the ingenious corollary which follows, that "since a given quantity of spike surface is, by hypothesis, of equal efficiency to the same quantity of ordinary flue surface, an excellent boiler may be constructed *without any flue surface at all!*" How any one could deduce such extravagancies from the well-known theory of conduction, is not for me to say. Doubtless under the influence of his imaginative powers, the reviewer had forgotten this theory; for, as Pope observes,

"Where beams of warm imagination play,
The memory's soft image melts away."

As a plain, matter-of-fact man, however, I beg to refer the reviewer to a diagram (see *Mechanic's Magazine*, No. 951, containing the very report from which he has so largely quoted,) describing an experiment which he may at any time make. He will there see two boilers described, having the same extent of flue surface, and in every respect alike, with this exception, that one was furnished with conductor pins,

while the surface of the other was plain. Yet, with the same measure of heat, (from thirty cubic feet of gas,) passing through the flue, the former evaporated 8 lb. 5 oz. of water, and the latter but 4 lb. 14 oz. Such experiments, which convince ordinary men, however, appear to have no effect upon this imaginative genius and hypothesis-monger, for he observes, of the value of practical experiments, that "though we cannot fail to be convinced by such an argument, we unhappily are not converted." "Unhappily!" I repeat. But we have good authority for saying,

"A man convinced against his will,
Is of the same opinion still."

On the second part of the reviewer's labours—respecting the "smoke-preventive plan," fearing to occupy too much of your valuable space, I will defer its consideration to my next communication.

I am, Sir,

Yours, &c.

C. WILLIAMS.

Liverpool, Feb. 16.

[We very much regret that Mr. Williams has not favored us with the remainder of his comments, as it is our particular desire that all controversial articles should be brought to a close as soon as possible, and not be allowed to take a range over the Journal for several months, we must therefore request that Mr. W. will conclude his communication in the ensuing Journal. We have received two or three other communications on the same subject, which for want of room we are obliged to postpone until next month, when we shall offer some remarks on their contents, as well as on Mr. Williams's communications.—Ed.]

SANDSTONE.

SIR—Will you allow me space in your valuable journal, to ask for information concerning sandstone as a *building material*?

I live in a neighbourhood which abounds in red and white sandstone, both of which are frequently used for building; but I have heard many complaints uttered against its use, on account of its great absorption of water, while others affirm that it is equally dry with brick work, provided it be used in the form of rubble work, and well flushed with mortar. It is important, in many places where sandstone abounds, to ascertain its nature with relation to its absorption, because its cheapness renders it very often desirable to use it. Some persons also have great objection to brick buildings, preferring the appearance of the sandstones from the neighbouring quarries, which often present in rubble work a very pleasing and picturesque appearance of warm tints of a variety of hues.

I am just about to build a house for myself, and should feel greatly obliged by any one favouring me with any facts connected with this subject, particularly as they are of general importance.

I am, Sir,

Your most obedient servant,
SANDSTONE.

[If our correspondents will refer to the second volume of the Journal, he will find some valuable information on all kinds of stone.—Ed.]

EVAPORATION OF WATER IN MARINE BOILERS.

SIR—Can any of your readers state the results of experiments made under their own observation on evaporation of water in boilers for land or marine engines of the usual construction; the results to be given in the following form:—Dimensions of boiler—Water evaporated in lbs.—Coals consumed in lbs.—Description of coals used—Time occupied in the experiment.

I think such information may be applied to some advantage.

Your obedient servant,

N. H. A.

[We refer our correspondent to Mr. Wicksteed's very elaborate experiments detailed in a work lately published, and which was noticed in the Journal of last year.—Ed.]

ON THE ORIGIN AND HISTORY OF THE OBLIQUE ARCH.

SIR—Your correspondent Oliver Twist, after describing the Loughborough and Stamford Road Bridge, on the Midland Counties Railway, makes the following assertions:—"The above is a unique specimen, being the only one ever erected, and is the bold invention of Mr. Woodhouse, and was erected in 1839–40." As the preceding is an incorrect statement, I beg you will insert in your next number this refutation, in order that, to use your correspondent's own words, "the real inventor may have his due meed of praise."

An oblique bridge of a precisely similar design was erected by Mr. Gibbs, the engineer, over the Croydon Railway, near the Jolly Sailor station in 1838, and I am informed that the peculiarities of the design were pointed out by that gentleman to Mr. Woodhouse during an examination of the system of longitudinal bearings adopted on the Croydon Railway.

Mr. Woodhouse would doubtless verify this statement, as I am convinced he would be unwilling to profit by your correspondent's inadvertency.

Feb. 23, 1842.

ALETHES.

BLECHINGLY TUNNEL.

This work, which is upon the line of the South Eastern and Dover Railway, is now completed: it is nearly three quarters of a mile in length, and is constructed through a hill forming part of the Wealden formation of geologists, consisting of a blue clay marl, most remarkably distorted by an upheaving force at some remote period, which has caused the hill to be full of faults, and occasioned considerable difficulty in the mining operations. In the course of the work the fossil remains of the Iguanodon and other reptiles have been found. The width of the tunnel in the clear is 24 feet, its height 21 feet above the level of the rails, with an invert having a versed line of three feet; its figure is elliptical. The work was carried on by means of twelve working shafts of nine feet diameter, and progressed with extraordinary if not unexampled rapidity, no less than 264 yards having been begun and completed in one month. The bricks were all made on the spot, and upwards of thirteen millions were made in the course of last summer, a considerable quantity having been previously made and dried in flues during the preceding winter.

The greatest number of men employed at one time was about 1,000, and only two men lost their lives in the course of the work, which casualties arose from their own imprudence when using gunpowder.

LIGHTNING CONDUCTORS.

Sir—I am about to put up an iron rod to a church tower as a lightning conductor, and you would oblige me very much by informing me in your next *C. E. & A. Journal*, whether the holdfasts may be iron also, or whether they must necessarily be of any other metal. I am not sure that if made of iron they would not conduct the lightning to the masonry.

Birmingham, Feb. 24, 1842.

AN OLD SUBSCRIBER.

[We are averse to the use of iron for hold fasts, although they are generally used for the purpose, if iron be used, we should recommend them to be of cast iron, as being more durable than wrought iron; but we advise that a supporter or holdfast be made either of glass, which can be cast very thick for the purpose, or of slate slab, both non-conductors of electricity, and not so liable to expand, or to be operated upon by the changes of the weather as metal—they can be let into the stone-work, and pinned in with cement. It is very advisable to see that the end of the conducting rod is let into the earth four or five feet.—Ed.]

STEAM NAVIGATION.

THE STEAM SHIP "LITTLE WESTERN."

We have taken an opportunity of visiting this vessel, in order that we might gratify our readers with a description of her machinery, which, on account of the peculiarity of its construction, and the reputed speed of the vessel, has become an object of considerable interest. The form of the vessel resembles that of the fastest Gravesend steamers, but sharper at both ends; the paddle wheels are of Morgan's construction. The ribs of the vessel are of Tiron; the exterior or shell is composed of plank about 4 inches thick. The boilers are of that description known as Spillers. Each boiler consists of a large internal chamber, in which the fire is situated, and above the fire several rows of brass tubes of about 2 inches in diameter are arranged in a direction differing by a few degrees from the horizontal line. The water is contained within these tubes which communicate with a water space at each end: the flame and hot air circulate *outside* of the tubes, and the deflection of their direction from the horizontal line has the effect of maintaining a constant current through each tube, thereby obviating the difficulty which has been found to attach to other tubular boilers, in which a pipe, if heated in the middle, has been found to generate steam which expelled the water out of each end, the elasticity of the steam preventing the water from again entering.

The engines are by Messrs. Acraman & Co., of Bristol, of 80 horse power each, and the nature of their general arrangement may perhaps be more clearly imagined by supposing a pair of common land engines to be turned upon their ends, that is, placed with the cylinder in a horizontal position, the cylinder being beneath and the connecting rods above. Upon the keelsons of the ship the two cylinders are laid horizontally with the usual space between them, and from each side of each cylinder a column arises to support the paddle shaft. The piston rod is attached by straps to a beam supported with columns in a vertical position, and from the upper extremity of the beam the connecting rod extends to the crank. The column which supports the one end of the beam centre is connected with the column which supports the one end of the paddle or intermediate shaft with three strong turned malleable iron stays, by the means of which the requisite stability is obtained. The inner end of each beam centre is prolonged sufficiently to support a short

lever, and each of these two levers works an air pump. The two air pumps therefore stand between the engines, at a distance from the line of the beam centres equal to the length of the levers.

The piston rod works through both ends of the cylinder; it is somewhat larger than piston rods for the same power usually are, is formed of brass, and is cast hollow. The steam and eduction valves are common double-beat valves of the same description as the expansion valves in common use. There are two steam and two eduction valves, as is the usual practice when spindle valves are employed. These valves are wrought by an eccentric upon the intermediate shaft. The spindle of one valve does not pass through the spindle of the other, but the whole four valves are arranged in a suitable chest above the cylinder. The operation of reversing is accomplished not by a loose eccentric, but by a double ended lever. The end of the eccentric rod, therefore, is made with two notches, and is maintained in the upper notch when desired, by means of a little sliding guard or shield.

The air pumps are of brass, and there is a marked peculiarity in their construction. The air pump pistons, instead of being provided with valves through which the water and air ascend preparatory to their being expelled during the *ascending* stroke, are made without valves, by which means the air and water are to be expelled by the *descending* stroke. In ordinary air pumps the piston is a *bucket*, in the air pumps of these engines the piston is a plunger. This species of arrangement has been previously tried, though with imperfect success. The air has been found to accumulate under the plunger, so that when the plunger was drawn up, the air, by expanding, filled the intended vacuum space, thereby preventing an adequate quantity of water from entering the pump chamber from the condenser. The consequence of this defective action was an imperfect vacuum in the condenser, and consequently an inadequate performance of the engine.

The evil of the accumulation of air beneath the plunger, might probably be corrected by causing the plunger to travel past the port, the lower side of the plunger being also made to slope downwards from the port. We are informed that in the *Little Western* there is no provision of this description, or of any other for correcting this evil, and we have further been informed that without any such corrective appliance, the evil is found to be inoperative or nonexistent. We confess we are unable to resolve this apparent inconsistency.

The advantages of the mode of construction of the air-pump pistons which Messrs. Acraman have adopted are eminent and manifold, and that any accumulation of air beneath the piston may be prevented by a proper arrangement we are thoroughly convinced. The greater part of the noise the working of an engine occasions, arises from the action of the valves in connection with the air pump, and there is much leakage often through them, and much wear and tear. Messrs. Acraman's arrangement will go far to prevent this, and the benefits of the system would be materially enhanced, if the action proper to the foot and delivery valves were accomplished by the agency of a simple form of slide valve. There would then be no noise at all, and the vacuum in the condenser would probably be something better than in ordinary engines; for in ordinary engines there must always be a difference of pressure between the air pump and condenser sufficient, with the difference of the level of the water to open the foot valve. The best engineers, by placing their foot valves nearly perpendicular, render the difference of pressure between the vapour in the condenser and that in the air-pump barrel, very inconsiderable, yet there is a difference in all ordinary engines, and this difference would be extinguished by discarding the foot and delivery valves in favour of a slide valve, which would accomplish the work of both.

The workmanship of the engines is very superior. There are no rust joints, but all the surfaces intended to be fitted are planed and made tight by a little red lead; there is no gasket joint between the cylinder and cylinder cover, but both surfaces are made quite true, and then a little red lead renders them perfectly tight. There are many advantages in this mode of fitting which we are happy to find is now adopted by the most eminent of our engineers. The pressure of steam in the boiler is 6½ lbs. The speed of the vessel is about the same as that of the *Eclipse*, *Railway*, and *Blackwall*.

The *Little Western* is certainly a favourable example of the skill of Bristol mechanics, but that there is anything either in the structure of the hull or machinery pre-eminently excellent, we utterly deny. In the production of the vessel there appears to have been too great a straining after novelty and there are evidences of a disposition to select arrangements, not so much by the consideration of what is excellent as of what is unusual.

The following are some of the proportions of the vessel and engines; she is 721 tons, measures between perpendiculars 200 ft., over all 216 ft., keel 195 ft., breadth of beam 27 ft., and including paddle boxes 47 feet, length of saloon 44 ft. by 24 ft. wide, ladies' cabin 20 ft. long.

The East India Company's Steam-frigate Memnon.—On Tuesday, 22nd ult., this splendid vessel, of 1,100 tons burden, mounting two 64-pounders, and four 32-pounder guns, and having them and all her shot on board, with about 300 tons of coals, and a heavy cargo sufficient to test her capabilities for a long voyage, left her moorings at Blackwall, and proceeded down the river in excellent style, for the purpose of ascertaining the efficiency of her engines and sailing qualities. The *Memnon* was built by Mr. Fletcher, and the engines, of 400-horse power, were constructed by Messrs. Maudslay, Sons, and Field, with copper boilers. The cylinders are double, the steam can be used expansively, and the consumption of fuel regulated to suit any circumstance of slow or quick sailing; she has also disconnecting gear to work one wheel without the other, if found necessary. On arriving at Longreach the full power of the steam was applied, and the engines worked beautifully, the vibration being scarcely perceptible; the large wheels, 26 feet in diameter, entered the water with such effect as to propel the vessel, with her heavy cargo, at the rate of 11½ miles per hour, affording the greatest satisfaction to her commander, Captain Powell, and all the gentlemen present. She proceeded as far as Sheerness before returning; the manner and simplicity with which the disconnecting gear (Mr. Field's patent) re-

moved the stupendous paddle-wheel and again attached it in an incredible short space was exhibited, it surprised the naval officers, who had never witnessed any thing of the kind before.

Royal Mail Steam Packet Company.—The *Medway*, another of this company's vessels, built by Mr. Pitcher, with engines of 400 horse-power, by Messrs. Maudslay, Sons, and Field, made an experimental trip down the Thames at the beginning of last month. She performed the trip to the admiration of all on board. The interior fittings combine both taste and convenience, and are in perfect accordance with the magnificence of the ship and engines. Another vessel, the *Trent*, with engines by Messrs. Miller and Ravenhill, was to leave the Thames for Southampton on the 27th ult.; we shall notice this vessel next month.

Plymouth, Feb. 14.—The sides of steam vessels on which coal boxes are fitted are ordered to be lined with sheet copper. This is in some measure to prevent the ship from taking fire, should (as on board the *Avon*) spontaneous ignition of the coals occur. Means for better insuring the safety of the crew and passengers, in the event of fire obliging them suddenly to abandon the vessel, are also now provided by the Board of Admiralty, at the recommendation of the committee of master shipwrights, ordering boats of two thicknesses of plank, lined between with felt, to be fitted to the paddle boxes of steam vessels.

Steam Navy.—It is in contemplation to increase the power of most of the steam frigates now in the service, the whole of which, with but one exception, are considered not to have sufficiently powerful engines for all the purposes for which a steamer may be required; that although their present power may answer very well in fair weather and smooth water, yet at the time their services are most required, in a squall on a lee shore, it will scarcely enable them to hold their own, much less to assist other ships. The *Devastation*, *Vixen*, *Geyser*, *Driver*, and *Styx*, are steam frigates of about 1,100 tons each. The *Devastation* is the only one of them that has sufficient power—her engines being 400 horse power; the engines of the others being only 285 horse power.

MISCELLANEA.

Railways Report.—The Officers of the Railway Department have presented a Report to the Earl of Ripon, President of the Board of Trade. This report, which is presented to Parliament by command of Her Majesty, is dated the 5th of February, 1842, and contains a voluminous mass of interesting information relative to railways. From the returns of accidents it appears amongst other things, that during the year 1841 the number of accidents on various railways, which arose from causes beyond the control of passengers, or, in other words, from carelessness, and want of proper precautions on the part of the railway companies or their servants, amounted to 29. By these accidents 24 persons were killed, and 72 injured. During the same year there were 36 accidents attended with personal injury to individuals, owing to their own negligence or misconduct, by which 17 persons were killed, and 20 injured; 60 accidents occurred which were attended with personal injury to servants of the company, under circumstances not involving danger to the public; by these accidents 28 individuals were killed, and 36 injured. Thus there were altogether 62 human beings whose lives were sacrificed by accidents on railways during the year 1841.

River Bourn, or Intermittent Springs of the North Downs.—In the Journal for March 1840, vol. iii., page 103, we gave some particulars of the outburst of this remarkable spring in the valley near the Half Moon Inn at Catterham Bottom, on the turnpike road from London to Lewis. We therein stated that the outburst at that time was remarkable for its having taken place at a much shorter interval of four years; however, in November last, being an interval of not quite two years, the spring burst again, and has continued flowing, without intermission, to the present time, and has given forth a much larger volume of water. We refer our readers to our former article for the particulars of this interesting phenomenon, and invite the attention of the scientific and the engineer to the subjects. To the latter it is important, as the occurrence of these springs are not unusual in the chalk formation, and at the last outbreak of the one in question, the engineers then constructing the works of the Brighton Railway suffered a serious inconvenience in consequence of it. It is most likely that the interval of the outbreaks depend upon the quantity of rain that may have fallen, as last year was remarkable for being very wet.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 27TH JANUARY TO 21ST FEBRUARY, 1842

Six Months allowed for Enrolment.

JOHN JAMES BAGGALY, of Sheffield, seal engraver, for "improvements in combs for the hair, and which are also applicable to combing other fibrous substances."—Sealed January 29.

JOSEPH HUGHES, of Whitehall Mill, Chapel-le-frith, Derby, paper maker, for "improvements in the method or process of manufacturing paper."—Jan. 29.

JAMES HUNT, of Whitehall, gent., for "improvements in the manufacture of bricks."—Jan. 31.

CHARLES WYKE WILLIAMS, of Liverpool, gent., for "improvements in the making and moulding of bricks, artificial fuel, and other substances."—Jan. 31.

HENRY FOWLER BROADWOOD, of Great Pulteney-street, Golden-square, Esq., for "an improvement in that part of a pianoforte, harpsichord, or other the like instrument, commonly called the name board."—Feb. 2.

WILLIAM NEWTON, of Chancery-lane, civil engineer, for "improved apparatus to be adapted to lace-making machinery, for the production of a novel description of elastic fabric from silk, cotton, woollen, linen, and other fibrous materials." (A communication.)—Feb. 8.

ADDERLEY WILLCOCKS SLEIGH, K. T. S. of Manchester, captain in Her M. P. Majesty's service, for "a certain method, or certain methods of effecting and forming sheltered floating harbours of safety, by the employment of certain buoyant sea barriers, applicable thereto, and which said improvements are also applicable to, and useful for, the formation of breakwaters, floating bridges, light-houses, and beacons, the protection of pier-heads, embankments, and for other similar purposes."—Feb. 8.

CHARLES HANCOCK, of Grosvenor-place, artist, for "improvements in printing cotton, silk, woollen, and other stuffs."—Feb. 8.

BENJAMIN BIRAM, of Wentworth, Yorkshire, Colliery viewer, for "improvements in the construction and application of rotary engines."—Feb. 9.

FREDERICK HARLOW, of Rotherhithe, carpenter, for "improvements in paving or covering roads and other surfaces, and in machinery for cutting the material to be used for those purposes."—Feb. 9.

ISHAM BAGGS, of King's square, Middlesex, chemist, for "improvements in obtaining motive power by means of carbonic acid, and also by a peculiar application of heated air."—Feb. 9.

CHRISTOPHER NICKELS, of York-road, Lambeth, gentleman, for "improvements in the manufacture of plaited fabrics."—Feb. 10.

WILLIAM BROOK ADDISON, of Bradford, in the county of York, manufacturer, for "improvements in machinery for spinning worsted and woollen yarn."—Feb. 10.

GEORGE JARMAN, of Leeds, flax and cotton spinner, ROBERT COOK, of Hathersage, Derby, heckle and needle manufacturer, and JOSHUA WORDSWORTH, of Leeds aforesaid, machine-maker, for "improvements in machinery for spinning flax, hemp, and tow."—Feb. 14.

JAMES ANDREW, of Manchester, manufacturer, for "improvements in the method or process of preparing or dressing yarns or warps for weaving."—Feb. 15.

CHARLES THOMAS HOLCOMBE, of Bankside, Southwark, iron merchant, for "certain improvements in the manufacture of fuel, and in obtaining products in such manufacture."—Feb. 15.

JOHN OSBALDESTON, of Blackburn, Lancaster, metal head maker, for "improvements in looms for weaving."—Feb. 15.

ALEXANDER ROUSSEAU, of the Strand, manufacturer, for "improvements in fire-arms." (A communication.)—Feb. 15.

GEORGE HADEN, of Trowbridge, Wilts, engineer, for "improvements in apparatus for warming and ventilating buildings."—Feb. 15.

JOHN LEWTHWAITE, of East-street, Manchester-square, engineer, for "improvements in steam-engines and boilers."—Feb. 15.

THOMAS RUSSELL CRAMPTON, of Lisson-grove, engineer, and JOHN COOPE HADDAN, of Moorgate-street, civil engineer, for "improvements in steam-engines and railway carriages."—Feb. 15.

ROBERT WORNUM, of Store-street, Bedford-square, pianoforte maker, for "improvements in the actions of pianofortes."—Feb. 15.

DANIEL GREENFIELD, the elder, of Birmingham, brass-founder, for an "improvement in the manufacture of hollow metal knobs for the handles of doors, and other locks."—Feb. 21.

MOSES POOLE, of Lincoln's-inn, gentleman, for "improvements in treating, refining, and purifying oils and other similar substances." (A communication.)—Feb. 21.

TO CORRESPONDENTS.

We have received a letter from Messrs. Braithwaite, Milner, and Co., in which they state that the apparatus for disconnecting the paddle-wheels of steam vessels is the invention and patent of Mr. Trewthill. They have also favoured us by a corrected drawing, showing the connection of the apparatus with the crank and the engine, which we shall insert next month, together with a communication on the same subject from Mr. Grantham.

The suggested improvement of Amicus Machinarum, on Messrs. Maudslays and Field's annular cylinder engine, by placing the air-pump in the central space will not do, the very object for which the annular cylinder was contrived, being for the purpose of getting a long connecting rod, is entirely lost in A. M.'s arrangement.

Δ. will be noticed next month.

The communications on pile-driving are again deferred, as we have not as yet come to any satisfactory conclusion as to the actual force of the ram.

B. R. We do not consider the apparatus for preventing accidents on railways would answer the purpose supposed by its inventor.

Agricolz.—We will endeavour, in some future number of the Journal, to give a table showing the variation of the Magnetic Needle yearly.

The Gorgon Engines.—We have received two communications in answer to "Vulcan," which we regret, on account of their importance, we are obliged to postpone until next month.

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, III, and IV, may be had, bound in cloth, price £1 each Volume.

THE INCLINED PLANES OF THE MORRIS CANAL, NEW JERSEY, UNITED STATES.

(With an Engraving, Plate IV.)

This canal is situated in the county of Morris, through the principal part of which it passes, and connects the two important rivers the Delaware and the Hudson. It is chiefly used for the transport of anthracite coal, which abounds in the Pennsylvanian mountains, to New York and other states. It was commenced in the year 1825, and finished in 1836, when it was opened. The construction is a work of considerable magnitude; it is in length 101 miles, and passes over an immense elevation of country, the summit being upwards of 914 feet above the Hudson, and 760 ft. above the Delaware. To overcome this great elevation, it would have been necessary to have had at least 200 locks, a number that would have occasioned great delay in the transit; it was therefore deemed advisable to have recourse to another mode of conveying the boats on those levels where there was a considerable acclivity in the section; for this purpose inclined planes were adopted, having an inclination, on the average, of one in 11, upon which are laid tram-ways for transporting the boats on trucks from the lower level to the upper level.

To show the magnitude of the work, we will give a few particulars of its construction. There are 18 locks on the Hudson side, having a total rise of 166 feet, and 7 on the Delaware side, 69 ft. rise; the locks are cased with stone, and are 78 feet long and 9 feet wide. Besides, there are 23 inclined planes, 12 on the Hudson side, total rise 748 ft., and 11 on the Delaware side, 691 ft. rise, there are also four flood gates at its junction with the two rivers, 5 dams, 30 flashes, 200 bridges, and 12 aqueducts, one that passes over the "Passaic" is of stone with an arch 80 feet span, and another of wood over the Pompton, 236 ft. long. The breadth of the canal at top is 32 feet, at bottom 20 ft. and in depth 4 ft. The works were first commenced under the direction of Capt. Beach, and afterward undertaken by Major Douglass, formerly Professor of the Military Academy at West-Point, who executed the inclined planes. One of the inclines 54 ft. high, cost 17,000 dollars, which is at the rate of 315 dollars per foot high.

We will now proceed to describe the inclined planes and the machinery, the object of our present notice:—

At the top of the inclined plane two chambers or locks are constructed of stone (figs. 1, 2, and 3) into which the boats are conveyed for the purpose of being lowered, or for their reception after they are drawn up; the upper end is divided from the canal T, by gates O, (figs. 7 and 8,) and the lower end by the gates O'; the upper gates are opened and closed by the aid of a small water wheel S', whose axis is prolonged and passes under the floor of the chamber to the partition N, and then turns two bevelled cog-wheels, *e, f*, each twelve inches diameter (see fig. 11); by the aid of a lever these wheels may be made to turn in either direction, they work into another bevelled wheel at right angles, which transfers the motion to the bevelled gear *i*, at the other end of the axis *h*, which also turns in either direction the two bevelled wheels *k, l*, upon the axes *l'* of these two wheels are small pinion wheels *m*, which work into the racks *n* on the face of the gate, and raise or lower the gate as may be desired. The gates O', (figs. 9 and 10,) at the other end of the chamber open upon a horizontal hinge joint, when open it lies flat upon the floor, and when shut it rests against the slanting pieces or stops *o*. For the purpose of filling the lock, the upper gates are lowered, which allows the water to flow over the floor of the chamber, and lift the lower gates, and as the water rises, so the gates are closed; when the lock is emptied, as the water lowers, so the gates O' drop down on the floor.

The emptying of the chambers is effected in the following manner: On the back of the upper gates are axes *k'* and *l'*, to which a chain *p* is attached, and fastened at the other end to a moveable board, *g*, ten inches high, connected to a bar *r*, attached to a horizontal sluice *s*, and in the floor of the chamber, which covers the outlet, P. If the upper gate O be raised, it prevents the water of the upper level flowing in, and at the same time the chain *p* is coiled round the axis *l'*, and consequently the board *g* and the sluice *s* are drawn forward, and a communication opened to the channel below P', through

which the chamber is emptied. When the upper gate *o* is lowered, the water rushes over, and by its force pushes forward the board *p*, and therewith the horizontal sluice *s*, and closes the aperture, at the same time closing the lower gates.

The machinery for moving the boats is under the floor of the chamber, and is set in motion by the aid of an overshot wheel (S, figs. 1, 2, and 3) 26 feet diameter, and 8 feet broad, made of wood, with a cast-iron shaft; upon this shaft is a cast-iron pinion wheel *d*, five feet diameter, which works into a cog-wheel *d'*, 4 feet diameter; upon a prolonged axis of this last wheel are two bevelled cog-wheels, 5 feet diameter, E E', (shown more at large in fig. 6) by means of the lever arrangements, either of these wheels may be made to revolve either way, as may be required to turn the horizontal cog-wheel *θ*, 7 feet diameter, the axle of which is under the centre wheel that divides the chambers; upon the top of this horizontal wheel is fixed the pulley 9 feet diameter *a*, round which the chain *d* passes, for the purpose of raising or lowering the truck.

Upon the inclined plane X X' are laid two pair of rails *x, x'*, $3\frac{1}{2} \times 1$ for the trucks to travel upon, and in the centre of each truck way is a pair of guide-pulleys, upon which the chain *d* runs.

For the purpose of conveying the boats there are two trucks (figs. 4 and 5 are a plan and elevation of one of them), the framing rests upon four longitudinal bearers *m''* upon which are laid 15 transverse bearers; on each side there are three vertical standards *n''*, fixed above by cross-stays *n*, and below by bolts and iron stays. They are supported upon four pairs of wheels, two pair *r'* are placed close to each other, and have in the centre a moveable axis, upon which the trucks can turn; at the end is a horizontal wheel *a*, round which the draw-chain *d* passes. When it is required to convey a boat from one level to another, it is generally done by having one truck at the top of the incline, in one of the chambers, and another at the foot in the lower level of the canal, the trucks stand in the water, and the boats are floated over and secured to them by a chain *d'* to the side-bar *t*. The boats are then drawn up by the aid of a strong chain *d*, (figs. 1, 2, and 3,) fastened at one end at *b*, and at the other at *a*, to *a*, sills fixed to the floor of the chambers, from *b* it passes down one side of the inclined plane X between the rails, then round the pulley *a'*, attached to the end of the truck, thence up again between the same rails to the chamber, where it passes through the floor L at *b*, to the underside, round the horizontal pulley *a*, and emerges again at *c*, it then passes down the other truckway X' round the pulley *a'* of the truck, up again, and terminates at *c'*, where it is fixed to the sill; thus when the truck is descending the chain is lengthening, and at the same time it is shortening with the ascending truck; by this arrangement the trucks nearly balance each other, and the only work for the water-wheel is to overcome the friction and the small difference in the weight of the up and down truck. There is also another help-chain fastened to the side of each truck, and which passes down the centre of the railway, over guide-pulleys, round a pulley at the foot of the incline-plane, which is for the purpose of drawing the ascending trucks up to the end of the chamber; as by the winding apparatus the ascending truck is only just brought to the top of the incline.

Fig. 12 shows the lever and break for regulating the speed of the water-wheel.

The boats weigh from seven to eight tons, and carry from 20 to 30 tons, the time occupied in passing up the longest incline of 1100 feet in length and 100 feet rise, is stated to be fifteen minutes, including stoppages. On account of their shorter length, the boats are not so long in passing over the other inclines. It is generally reckoned that about six boats can pass each way per hour. The machinery can be managed by a single person, the boatman having nothing to do but to fasten the boat on to the truck.

MEASUREMENT OF BRIDGES.

SIR—Will you allow an old friend to ask, through the medium of your very able Journal, some of your very valuable correspondents the best method of measuring a stone bridge? taking the different parts of the works separately, and you will much oblige,

Yours very sincerely,

PETAUS.

Dublin, March 12, 1842.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XXXVI.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. It would seem that architects neither keep any journals, nor carry on any correspondence relating to their professional pursuits and engagements, for nothing of the kind has at any time been communicated to the public, not even as regards such men as Adam, Wyatt, and many others whose intercourse with the higher ranks of society must have given some sort of historical interest to their epistolary correspondence, supposing they ever wrote any letters not strictly confined to mere matters of business. While Joey Grimaldi the pantomime clown obtains a biographer who bestows upon him a couple of volumes, Sir Jeffry Wyatville has not been thought worthy of any such compliment, notwithstanding that he was for some time within the sphere and atmosphere of a court, and that a life of him would, no doubt, serve as an excellent peg on which might be hung numerous anecdotes relating to very distinguished personages, including the conversations which he must no doubt have held from time to time with his royal patrons on the subject of architecture. Some day or other, perhaps, the world will yet be enlightened, and some fortunate publisher will be able to announce the "Wyatville Papers and Correspondence."

II. It is excessively provoking to meet so repeatedly with paltry "put-off" excuses for reticence of criticism in regard to contemporary works of architecture, as though they were not just as much amenable to opinion and comment as the productions of any other art, but were entitled to especial forbearance. It is after such fashion that Gauthier apologizes for not offering any remarks on the design of the new theatre at Genoa (erected by Carlo Barabino, 1826-8), saying he chooses "to abstain alike from commendation or from censure, leaving it to the public to appreciate its merits"! Leaving it to the public, forsooth!—and how is the public to form its judgment if critical inquiry is to be stifled, and those who are, or who ought to be, capable of delivering opinion on such matters, abstain from doing so? Without any great breach of charity, we may, in all such cases, attribute the apparent candour and forbearance either to the writer's having no real opinion of his own to express, either one way or the other, or to a ridiculous excess of cautiousness. Why there should be aught more invidious or indelicate in criticising the productions of a living architect, than in exercising the same freedom of judgment on those of a living painter or poet, it is not easy to perceive. Criticism may knock a poem on the head at once, and cause it to drop dead from the press—but criticism cannot knock down stone walls; a building will remain either to confirm, if correct, or refute, if unjust, the opinion passed upon it. It must be allowed that architectural critics are liberal enough in favouring us with established opinions, which may be come at without other trouble than that of copying them from other books, and which are most conveniently safe, inasmuch as the critic himself hazards nothing, for if the opinion be approved, he can take the credit of it, and if taxed as unsound, can throw the odium of it on the stupidity of those from whom he borrowed it. "But," exclaim some, "we do not want criticism—we have gone on very comfortably without it. Criticism does far more harm than good; it teaches the public to pry into what they have no business to fancy they can understand, whereas all that we require of them is their implicit admiration."

III. Though we have had many modern architectural works relative to the principal cities of Italy, they have all of them been exclusively retrospective or nearly so, exhibiting only the monuments of former periods of the art, and showing scarcely a single recent example. Admitting that the subjects selected for them are of more intrinsic value as studies than any buildings of recent date, still some of the

latter would at least possess the interest of novelty. Architecture is not absolutely defunct in Italy, although it might almost be imagined that it had not produced a single work of any note since the commencement of the present century, so little is the information to be met with relative to any edifices that have been erected there within the last forty or fifty years. It would seem to be an express rule adhered to by all our tourists, architects, and artists, who visit that country, not to take any notice of contemporary buildings—on no account to describe or to delineate them, but to bore us for the ten-thousandth time, with their extacies, with the Pantheon, and St. Peter's, with Palladio and Michel Agnolo. If they can bring home nothing less stale, they would do well neither to take up their pens nor open their mouths. Of Cagnola they of course have never heard, Possagno they have never visited, nor have they ever stumbled upon the Café Pedrocchi at Padua—a palazzo in appearance, and a sufficiently striking specimen of the modern Greco-Italian school—with much elegance to recommend it, though not free from defects. Although it may not be ranked among the public edifices of that city, it is, as a piece of architecture, quite as conspicuous an object as the Reform Club House, which last, perhaps, a tourist through Pall Mall would not have eyes to discover. A work containing examples of the Italian architecture of the present century, would be a welcome novelty, and though the buildings themselves may be comparatively few and far between, still, ample materials for the purpose are to be collected between Milan and Naples, from the structures by Bianchi and Niccolini, in the last mentioned city, to Buonsignore's church, the Madre di Iddio, at Turin, and Canova's Doric rifacciamento of the Pantheon, at Possagno. But ———! and that, if not the most satisfactory, is certainly a most omnipotent reason wherefore nothing of the kind either is, or is likely to be undertaken.

IV. That theory which would base architectural beauty upon utility and fitness, is so far from being satisfactory as clearly tracing the source of the former quality to the two latter, that, instead of removing perplexity, it rather increases it. In direct opposition to such doctrine, every-day experience convinces us that so very far from constituting æsthetic beauty, mere utility and fitness contribute very little at all towards it, even in architecture, where, as far as the purpose of building is concerned, they might seem to be not only indispensable, but all-sufficient, and afford all the pleasure which the mind can derive from examining and contemplating edifices of any kind. Yet such is assuredly not the case; on the contrary, it is only when it aims at something more than utility, when it indulges in the superfluous—or, if you will, the useless—in short, when it steps into the province of art, and aims at the idle gratification of the eye, that architecture is entitled to the high distinction claimed for it, and the lofty pretensions set up in its behalf. Upon the utility principle of beauty, a turnip field would be a far more agreeable prospect than any to be met with in Swiss or Italian scenery; and upon the common-sense fitness and utility principle, a modern church erected according to the "cheap and nasty" system, and according to Islington or Bethnal Green taste, ought to delight quite as much as, if not more than, any of those glorious examples of our ancient ecclesiastical architecture which so wonderfully impress the mind. Unless the word "utility" be exceedingly elastic, indeed, and its meaning so ductile that it may be drawn out like gold to a most prodigious extent, utility cannot at all be said to recommend the dome of St. Paul's, it adding nothing whatever to the serviceableness of the building; while on the other hand, the unwieldy platforms or galleries with which our churches are encumbered, ought to be accounted beautiful, since they certainly have the plea of being useful, as far as affording sittings goes.

V. What a writer in the Art Union has remarked relative to works of sculpture exhibited in this country, will apply equally well to architecture. "The last slight which this noble art sustains remains untold; see our daily and weekly papers, nay, our journals of art and science, see the column after column noticing the productions of the pencil, and the infantile paragraph, stating simply that sculpture too is there." By merely changing a single word, and reading "architecture," or "architectural drawings," instead of "sculpture," we

have here described the sort of attention bestowed by the critics of the periodical press upon exhibited designs. Opinions as to their merit they do not put forth, since they are unable either to form or to express any; but it is considered quite sufficient if the "infantile paragraph" be tacked on to the rest, by way of postscript in some such terms as "there are several beautiful architectural drawings, on which our space will not permit to bestow more particular notice." Or else "particular notice" goes to the extent of copying titles and names from the catalogue, ticketed, perhaps, by some luminous epithet, which leaves us just as much in the dark as ever with regard to the things so mentioned. For this neglect, architects have, in a great measure, to thank themselves; first, for presenting their designs before the public at the far end of an exhibition of pictures, thrust into a little poking room where not above one third of the drawings hung up can be seen, much less examined. Secondly, because they do nothing whatever towards promoting a popular relish for the study of architecture, and vindicating the pretensions assumed for it as one of the fine arts. They at least have not much right to complain of their designs being passed over without notice at exhibitions, when, by the kind of notice they themselves generally bestow upon them in their own publications, they convince us that they are unable to explain their own ideas, or point out the effect and character at which they aimed. Ill does it become architects as a body to regret that there should be so much apathy on the part of the public towards their art, when they themselves display a degree of apathy still more unaccountable if not very much more discreditable.

MESSRS. MAUDSLAYS AND FIELD'S MARINE ENGINES.

It must be unnecessary to offer a single observation upon the value of the annexed table. Its value will, we are confident, be fully appreciated by our readers.

It is proper to remark, that several of the sizes not given directly in the table are involved in other sizes which are given, and may be deduced from them by a very simple process. Thus the length of the stroke of the air pump, as well as of the hot water or feed pump, are not given directly, but may at once be ascertained as follows:

Given—Length of stroke of cylinder.

" Distance from centre of beam gudgeon to centre of cylinder.

" Distance from centre of beam gudgeon to centre of air pump.

From these data the length of the stroke of the air pump may easily be obtained; we have only to work this simple rule of three question;—Distance from centre of beam gudgeon to centre of cylinder is to distance from centre of beam gudgeon to centre of air pump, as length of stroke of cylinder is to length of stroke of air pump: whence we obtain the answer sought for at once. It is manifest that the answer may also be obtained by construction. The feed pumps are, in Messrs. Maudslays' engines, as well as in most other engines, worked off the air pump cross head; the length of the stroke of the air pump, therefore, determines the length of the stroke of the feed pump.

The sizes given in the table have manifestly reference only to side lever engines. The size of the steam pipe is not given in the table, but the size of the steam port is, and the steam pipe should be, about the same area. The quantity of lap or cover proper to be put upon the valve, is a question determinable altogether by the quantity of expansion required, and varies in different engines of the same power. But the upper and under faces of the valve are, in Messrs. Maudslays' engine, in no case of the same breadth: the cause for this inequality is that if the valve be at half stroke, that is, both ports closed, and if the engine be moved round, the travel of the valve from half stroke to the extremity of the stroke *downwards* will be found to be not the same as the travel of the valve from half stroke to the extremity of the stroke *upwards*. In other words, the space described by the valve whilst the piston descends, and the space described by the valve whilst the piston ascends, are not equal; whereby it becomes necessary to make the superior and inferior faces of the valves of different depths, to compensate for this inequality.

The accuracy of the preceding statement every engineer has it in his power to verify, either by a model, or by a drawing of the valve and piston in their several relative positions. The cause of the irregularity may be traced to the oblique action of the connecting and eccentric rods. If the piston be placed at half stroke, that is, midway between the top and the bottom of the cylinder, the crank will not be level. This is manifest from the ordinary method of ascertaining the length of the connecting rod, which is to level the beams, and take the vertical distance from the extremity of the beams to the centre of the crank shaft. When the beams are level the engine is at half stroke, but if we wish to attach the connecting rod to the crank pin—its length being ascertained as above—it will be necessary to bring the crank down a little, to compensate for the depression of the head of the connecting rod due to the deviation from the vertical line. If, then, the crank be not level at half stroke, the descent of the piston from half stroke, and its ascent to half stroke again will accomplish more than half a revolution of the paddle wheels; and the ascent of the piston from half stroke, and its descent to half stroke again, will accomplish less than half a revolution of the paddle wheels. The ratio of the disparity will vary with the length of the connecting rod, the circumstance of there being overhang or no overhang of the beam, the length of the beam, and other circumstances; but in all ordinary engines, the difference between the upper segment of the circle of the crank's revolution and the under segment of that circle will interfere with the valves' motion, and the proportionment of the valve faces ought to have reference to the extent of that interference.

It is Messrs. Maudslays' practice, in some of their very recent engines, to make the stroke of the valve considerably more than twice the depth of the port. All the valve levers are equal, and the stroke of the valves is in all cases equal to the throw of the eccentric. It is also their invariable practice, in all engines of considerable magnitude, to construct the valve casing with a faucet joint, to permit the expansion of the casing when heated with steam, without distorting the cylinder. In some large engines which have been without this provision, we have known the cylinder ports to be rent asunder by the expansion of the casing; and however frequently and however well the rust joints of the casing might have been made, they invariably became very soon leaky, from the effect of unequal expansion. The cylinder when hot will expand as much as the valve casing; and if the two were always equally heated, no detriment could ensue from the absence of an expansion joint. But as the throttle valve is never perfectly tight, and as the slide valve generally is so, the steam before the engines are started enters the casing and induces its expansion; whilst being excluded by the slide valve from the cylinder, the cylinder is not heated, and therefore does not expand. Injury of some sort or other, if the engine be large, is sure to be the result of these conflicting forces. Our provincial engineers are sadly deficient in their acquaintance with or their attention to details such as those to which we have adverted; yet it is upon an attention to such details that the superiority of an engine principally depends.

In the double cylinder engines of the Messrs. Maudslays, cylindrical slide valves are employed, and have been found to operate extremely well. The packing of these valves is metallic. The packing of the pistons made by the same firm are invariably metallic, and generally consist of a single ring turned eccentric, cut in one place, and the cut part fitted with a tongue piece to prevent the steam from passing through the cut. A piece the same breadth as the ring is fitted over the back of the cut, ground tight, and then rivetted to one part of the ring. The elasticity of the ring is in most cases found sufficient to keep the ring in intimate contact with the interior of the cylinder, and the force with which this contact is maintained may be either augmented or diminished by a bridle—a truly ingenious contrivance, and one which we regret the limits of this notice prevent us from referring to more specifically.

In a future paper we shall probably enter with considerable minuteness into the merits of Messrs. Maudslays' machinery, or rather into those details which constitute the excellence of the machinery of that eminent firm.

PROPORTIONS OF MARINE ENGINES.

THE following Table of Proportions is collected from Marine Engines of Messrs. Maudslays' manufacture.

HORSE POWER .	10	15	20	25	30	40	50	60	70	80	100

DOUBLE CYLINDER STEAM ENGINE.

Description of a Double Cylinder Rotative Steam Engine, erected by MESSRS. G. and J. RENNIE, at Mr. Thomas Cubitt's Factory, near Vauxhall Bridge.

This engine is entitled to the attention of all who are interested in the economical production of steam power. For a rotatory engine its consumption of fuel is believed to be unprecedentedly small; and we are convinced we shall render an acceptable service to our readers by informing them of the peculiarities of its structure, and the nature of its performance.

The arrangement of the parts of the engine is identical with that of the beam rotative engines in common use, with the exception that the motion is derived from two cylinders instead of from one. The employment of two cylinders, the pistons of which are worked by the same steam, was first practised by Hornblower, and extended and improved upon by Woolfe; but the plan has never come into general use. In this engine the smaller cylinder is one-fifth of the capacity of the larger cylinder, and the expansion takes place in the larger cylinder exclusively. The steam enters the smaller cylinder direct from the boiler during the whole of the stroke; and having pressed down the piston, escapes, not into the atmosphere or into the condenser, but into the larger cylinder, where it becomes instrumental in forcing the piston of the larger cylinder upwards. The same steam, therefore, is rendered available in the production of power in both of the cylinders, and it is only after having accomplished this end that it escapes into the condenser.

The piston rods proceeding from the cylinders are attached to the same end of the beam, the rod of the larger cylinder at the extremity of the beam, and the rod of the smaller cylinder at a point nearer the main axis. The pistons, therefore, act in concert; and by a proper arrangement of the valves, a communication is maintained between the space beneath the piston of the smaller cylinder and the space above the piston of the larger cylinder, so that the pistons descend simultaneously.

The engine is supplied with steam by one boiler, which is cylindrical, and is, in its details, of the most approved Cornish construction. The exterior diameter of the boiler is 6 ft. 3 in., the extreme length 34 ft., and the pressure of the steam 28 lb. upon the square inch. The fire grate is situated in an internal flue tube, 3 ft. 8 in. in diameter, which extends through the boiler, from end to end. The length of the fire-place is 4 ft. 6 in., its breadth 3 ft. 8 in., and its mean height 18 in. The coal burned is Graigola, an excellent and economical species of Welsh coal, which produces no smoke. The depth of coals upon the fire bars is never permitted to exceed 3 inches, so that there is little or no carbonic oxide generated. The combustion is slow, a condition favourable to its perfection, and as the intensity of the fire scarcely exceeds that of a common household grate, there is no clinker formed. The fire bridge is composed of brick, and instead of being flat upon the upper surface, as is the case in many boilers, is formed to a circle nearly concentric with the circle of the flue tube, and leaving only a few inches of opening between the convex surface of the bridge and the concave surface of the flue tube. By this expedient the flame and hot air proceeding from the fire are spread in a thin sheet over the interior surface of the flue, by which means their heat is more rapidly and perfectly communicated to the water in the boiler.

Between the fire bridge and the farther extremity of the boiler a tube extends longitudinally through the flue. This tube contains water; it is about 25 inches in diameter, and communicates in two places with the water in the boiler. One of these communications is through a vertical pipe, extending from the under side of the flue tube to the under side of the horizontal pipe containing water, and situated immediately behind the bridge. The other communication is through a copper pipe at the after extremity of the boiler. This pipe is 3½ in. in diameter; it springs from the upper side of the horizontal pipe,

and, passing to the outside of the boiler, ascends until it reaches the level of the boiler top, when, bending over, it penetrates the shell of the boiler, and descends internally until it reaches to the depth of a few inches below the water level. Through this arrangement of pipes a continual current of steam and water is maintained.

The hot air, upon leaving the furnace, travels through the internal flue, communicating its heat both to the water in the boiler and to the water contained in the horizontal pipe situated in the flue which we have just described. Upon arriving at the extremity of the internal flue, the current of hot air is separated into two streams, one of which traverses the one side of the boiler, and the other the other side of the boiler. These streams, upon arriving at the front of the boiler, again unite; they then descend, and pass longitudinally beneath the bottom of the boiler, after which they enter the chimney. In the passage which unites the flue beneath the bottom of the boiler with the chimney, a long pipe is placed about 15 inches in diameter, and into this pipe the water employed for feeding the boiler is first introduced. By this arrangement the air proceeding to the chimney is robbed of its superfluous heat, and escapes into the atmosphere at a comparatively low temperature.

The pressure of the steam in the boiler is indicated by a syphon mercurial gauge, graduated to feet, inches, and quarters of an inch. The level of the water in the boiler is regulated by a feed cock, adjusted from time to time by the engineer. The usual apparatus for feeding by a head of water, with a valve operated upon by a float, would require to be of inconvenient dimensions if applied to this boiler, on account of the superior pressure of the steam to that of ordinary land boilers. There is a glass gauge tube and the usual gauge cocks for the indication of the water level.

The boiler is furnished with two steelyard safety valves, and one safety valve situated within the boiler and inaccessible to the engineer. Four brick walls enclose the boiler, and a 9-inch brick arch extends over its top. Between this arch and the external surface of the boiler a space of an inch or two is left, to leave room for the expansion of the boiler. Above the brickwork there is a layer of charcoal about a foot in depth, for the purpose of preventing the escape of heat from the boiler; and the precautions adopted have the effect of rendering the escape of heat so trifling that it is nearly imperceptible.

The interior diameter of the steam pipe is only 3 in. Upon stopping the engine, the eccentric rod is not thrown out of gear, as is the usual practice, but a cock in the steam pipe is shut, whereby the admission of steam to the engine is totally prevented, and the quiescence of the engine is the result. The cock by which this is accomplished is a four-way cock, one of the channels through it being for the purpose of maintaining the communication between the boiler and the slide valve, and the other for accomplishing the operation of *blowing through*. The slide valves are of the common three-ported description, and are situated at the upper extremities of the cylinders. The covers of both cylinders are upon the same level, but the larger cylinder being the longer projects downward further than the smaller one. This peculiarity, however, is not observable to a spectator: the symmetry of the work has been carefully and successfully preserved. The valves move simultaneously, and are put in motion by arms extending from stout iron rods, which ascend through the floor of the engine-room, and are guided in sockets attached to the respective cylinders to which the valves belong. These rods derive their motion from a cross head which forms the upper side of a square frame, in which a heart-shaped cam revolves, by which means the frame is moved alternately upwards and downwards, the sides of the frame being so far apart that the cam passes them in its revolution, without communicating any lateral motion. This arrangement has been long known under the name of *the heart motion*, but its extended employment has been prevented by the impression that it produced a jarring and irregular motion, unfavourable to the smooth working of machinery. This impression is, in the present case, proved to be unfounded: the valves are moved without noise, tremor, or harshness of any kind. The advantage to be derived from the use of the heart motion is a rapid opening and closing of the port; but we believe the eccentric to accomplish this

operation with sufficient rapidity, if the ports be made of proper dimensions.

The cam is made of steel, and the upper and under surfaces of the square frame against which the cam presses are covered with plates of steel, about three-quarters of an inch in thickness. The cam is bolted upon a cast iron chuck, keyed upon the end of a horizontal shaft, about 3½ in. in diameter, which derives its motion from the main shaft of the engine, at the same point where the governor derives its motion. The square frame presses against this cast iron chuck, and is steadied by it.

The beam, parallel motion, connecting rod, crank, fly wheel, &c. are of the usual description, and therefore require no particular notice. The slide valves are, as we have already mentioned, of the description known as three-ported. There is a loss of steam from the use of this kind of valve. We consider a double two-ported valve to be in every respect preferable. The governor is supported by a frame placed immediately over the crank shaft, and the connection between it and the throttle valve is maintained by a rod which runs beneath the floor of the engine house. The diameter of the cold water pump is 10 in.; the length of its stroke 2 ft. 5½ in. The diameter of the air pump is 20 in.; the length of its stroke 3 ft. The delivery valve is situated in the mouth of the air pump; it is of the pot-lid construction, but by a partial application of the principle of equilibrium, the noise and force with which common pot-lid valves shut are greatly abated. A valve so constructed as to be in perfect equilibrium would manifestly not work in an air pump, as no upward pressure would open such a valve; but by the combination of the principle of the equilibrium valve with that of the ordinary pot-lid or spindle valve, a point of adjustment may be arrived at where the valve will open with sufficient facility, without being closed with an injurious force.

This will be better understood by the annexed section and plan of the delivery valve. For this sketch, as well as for the indicator diagrams which accompany this article, we are indebted to the Messrs. Rennie.

Fig. 1.—Section of Valve.

a a a a a Fig. 1., is one half of the valve proper, or that part which rises to permit the escape of the air and water lifted from the condenser by the air pump; *b b b b b* is one half of the valve seat, or that part which remains stationary, and against which the valve strikes. The valve seat is bolted by six bolts to the mouth of the pump, by bolts which pass through the holes *x x x x*, Fig. 2. The amount of force with which the valve is closed is that due to the pressure upon the horizontal surface *A*, Fig. 1, on the ring *A A A A*, Fig. 2, whilst the real area through which the air and water escape is that represented by *B*, Fig. 1. Whatever pressure exists upon the side of the valve *C*, is balanced by the equal and opposite pressure upon the other side *C*. It is manifest that the more nearly the faces *f* and *f'* are brought into the same vertical line, the less force will the pressure above the valve exercise in shutting it, and the greater will

be the force requisite to open it; and if the faces were brought into the same line, no force that the greatest pressure beneath the valve could produce would ever open the valve.

Fig. 2.—Plan of Valve.

The species of valve applied to the air pump of this engine is certainly superior to that employed in engines in general; but we believe that the application of the slide valve to air pumps would be preferable still. One slide valve would perform the united functions of the foot valve, the bucket valve, and the delivery valve. The air pump piston might then be made without any opening through it, the water being expelled from the air pump by expression; and if the piston were made to travel a short distance beyond the port, no accumulation of air could take place in the pump chamber. We cannot enlarge upon this topic further than to say, that by using a slide valve worked by the engine, a better vacuum might be attained in the condenser than by any species of valve which is opened by the difference of pressure upon its two sides.

A certain quantity of the power which an engine exerts is exerted in overcoming its own friction, lifting the water which has accomplished the condensation of the steam out of a vacuum, &c. The term horse power is used to denote the available quantity of power which an engine is capable of furnishing for any useful purpose, and is, therefore, the excess of the power produced over the power consumed by the engine itself. Any estimate of the power of an engine, based upon the assumption that the whole power exerted by the piston is the true measure of the engine's beneficial exertion, is, therefore, fallacious. An allowance of one-eighth of the power as being consumed by the engine itself, is a usual and moderate allowance.

The amount of economy to be obtained from steam working expansively is precisely the same, whether the expansion takes place in one or in two cylinders. The use of two cylinders serves to equalize the action and to diminish the strain thrown upon the moving parts; but it is questionable whether the greater fluctuation of pressure when only one cylinder is used might not be rendered equally instrumental in the production of a regular motion, simply by using a larger fly-wheel, or driving the fly-wheel at a greater velocity, and whether it is not quite as simple to increase the strength of the moving parts a little, as to add an additional cylinder and piston, to prevent them from being subjected to so great a strain.

Fig. 3.—Indicator diagram of Small Cylinder.

Fig. 4.—Indicator diagram of Large Cylinder.

A L, Atmospheric Line.

It is easy to determine analytically the amount of advantage that is to be derived by using steam expansively. Let the full pressure of steam upon the piston be represented by unity, and let x represent the capacity of the larger cylinder, or the space through which the piston has been moved, whilst urged by the expanding steam. The density will then be $\frac{1}{1+x}$ and assuming that the densities and elasticities are proportionate, $\frac{dx}{1+x}$ will be the differential of the efficiency, and the efficiency itself will be the integral of this, or, in other words, the Napierian logarithm of the denominator. Wherefore the efficiency of the whole stroke, whether the expansion is accomplished in one or in two cylinders, will be $1 + \text{Nap. log. } 1+x$.

Taking the pressure of the atmosphere at 15 lb., and the pressure

upon the piston at the commencement of the stroke at 25 lb. above the pressure of the atmosphere, then $15+25=40$ lb. If the steam be cut off at one-fifth of the stroke, or if, as in the present case, the smaller cylinder be one-fifth of the capacity of the larger cylinder, the steam will be expanded into 5 times its original volume. Its pressure, therefore, at the termination of the stroke, will be $\frac{40}{5}=8$ lb., or 7 lb. below the pressure of the atmosphere; but as the average vacuum in the cylinder of an engine rarely much exceeds 24 in. of mercury, or 12 lb. pressure, the unbalanced force of the steam, or the force of steam urging the piston at the end of the stroke will be $12-8=4$ lb. When the steam is cut off at one-fifth $x=4$. The efficiency, therefore, is $1 + \text{Nap. log. } (1+4)=1 + \text{Nap. log. } 5$.

The Napierian logarithm of 5 is 1.6094379, therefore the total efficiency of the steam is 2.6094379, instead of 1. In other words, the

PERFORMANCE OF ENGINE.

The engine makes 19 double strokes per minute.

The consumption of fuel is 132.3 lb. of unscreened Graigola coals per hour.

The area of the smaller cylinder, less $\frac{1}{4}$ the rod, is 186.24 square inches.

The area of the larger cylinder, less $\frac{1}{4}$ the rod, is 749.29 square inches.

The number of feet per minute travelled by the smaller piston is 171.

The number of feet per minute travelled by the larger piston is 228.

The mean pressure in the smaller cylinder urging the piston, as shown by the indicator, is 25.56 lb. upon the square inch.

The mean pressure in the larger cylinder urging the piston, as shown by the indicator, is 6.9 lb. per square inch.

We subjoin indicator diagrams, taken from both cylinders, in the ordinary working condition of the engine.

We are informed by Mr. G. Rennie that the nominal power of the engine is 40 horse power, but that the actual work performed, or power exerted is—

By the smaller cylinder . . .	24.6
By the larger cylinder . . .	35.6

Real number of horses power of engine	60.2
---	------

It is right, however, that we should investigate this point for ourselves.

The area of a surface included within the lines of an indicator diagram is a correct representation of the power really exerted by an engine, but the mode of finding a numerical expression for that area by means of ordinates is not perfectly correct; although if there be a sufficient number of ordinates, it may be rendered sufficiently correct for practical purposes. We shall, therefore, take the mean pressure in the smaller cylinder at 25.56 pounds, and the mean pressure in the larger cylinder as 6.9 pounds, as determined by Mr. Rennie.

$$\begin{aligned} 186.24 \times 25.56 \times 171 &= \\ 814010.3424 \div 33000 &= 24.6 \\ 749.29 \times 6.9 \times 228 &= \\ 1178782.628 \div 33000 &= 35.7 \end{aligned}$$

60.3

4

Real number of horses power	52.76
-----------------------------	-------

efficiency of the steam is rendered one and a half times greater by being so used as to be expanded into 5 times its original volume. This result is perfectly independent of the pressure of the steam employed; but if steam of a considerable pressure be not employed, the cylinders will require to be of inconvenient dimensions. The idea entertained by some persons, that the cause of the economy in the Cornish and other engines which use high pressure steam expansively, lies in the inconsiderable difference in temperature between steam of the pressure of one atmosphere and steam of the pressure of several atmospheres, is perfectly fallacious. Temperature is not in all cases a measure of the comparative quantities of heat resident in bodies. Two cubic feet of steam of the pressure of one atmosphere will, if compressed sufficiently, become about one cubic foot of steam of the pressure of two atmospheres; and whatever may be the temperature of the steam in the two states, the quantity of heat existent in it will be in each case the same.

In common rotative engines, which operate without expansion, the ordinary consumption of coal is 10 lb. per horse power per hour. But the horse power is usually found to be about 52,000 lb. raised one foot high in the minute, which is equivalent to 26·208 millions raised one foot high by a bushel or 84 lb. of coal. Some good engines, however, operate with an effective pressure upon the piston of $13\frac{1}{2}$ lb. per square inch=60,000 raised one foot high for a horse power; and a few ascend as high as 66,000 per horse power, without employing high pressure steam. The engines consume about 8 lb. of coal per nominal horse power, or 4 lb of coal per horse power of Watt. The consumption of coal in this engine is $132\cdot3$ lb. per hour $\frac{132\cdot3}{52\cdot76} = 2\cdot5$ lb. per horse power per hour.

We recommend this engine to the notice of all who are interested in steam machinery. By the use of the Graigola coal, smoke is altogether avoided, and this species of coal is moreover extremely lasting and economical. The engine is elegantly finished; its parts are skilfully and tastefully arranged, and the details of its construction manifest the supervision of the skilful mechanic. In the economy with which it performs its work this engine stands in the first rank; and it certainly works with a smoothness, efficiency, and equability, it would be difficult to surpass. As a specimen of workmanship, as well as an achievement of engineering skill, it is destined to confer much honour upon the Messrs. Rennie.

METROPOLITAN IMPROVEMENT SOCIETY.

Whoever has, in any degree, reflected on the architectural movement, which was such a prominent feature in the Georgian era, and is equally so at the present day, must have felt strongly the necessity of some general plan, and of a central controlling body. Whether we look at what has been effected, or what is left undone—whether we regard the useful or the ornamental, the imperfection of the present measures has been evident, and the growing disposition towards remedying this defect. Who thinks of the old city, and looks at the new one which has now risen, without regretting that so many spots where improvement is urgently called for, should have been left untouched? The men of the present day have thrown off the dulness and puerility which infested England in the time of the second and third Georges, and it is plain that we have taken steps to redeem our metropolis from their neglect. Such a period of repose was perhaps wanted after the violence of the civil wars, and the dissoluteness which prevailed under the second Charles. It might be in the social body, as in the human system, that irregular excitement must be succeeded by as great a collapse; and never perhaps was the depth of the bathos so extremely felt in this country as when equally in arms, in literature, and in art, with few, and those not first-rate, exceptions, we had nothing but mediocrity. Nor was the passive endurance of dulness the sole evil there was—a power of warfare active against whatever of beautiful and great our ancestors had left, music was made not only an exile but an alien, painting defunct here was exercised only at the hands of foreigners, and the whitewash brush, which so mercilessly attacked the arts of design in our buildings, was wielded not less energetically

in the world of letters. The age of pigtailed and milk and water was not contented with self-disfigurement, the same artist who had spoiled his own head, clapped periwigs on the heads of the Romans: and both the country and the theatre witnessed caricatures not only of the proprieties of particular ages, but of human nature itself. The puritans destroyed, the cavaliers disguised, and the Hanoverian dulness finished whatever the presumption of the restoration had left untouched. The dawning of the present movement, the glimpses of better days, which were seen even in the worst, and the processes by which even evil features were made to work good, would take too long a history to sketch now—we must be contented with the result. We have a metropolis which, both in historical remembrances and existing monuments, has all the elements of grandeur and beauty which the most magnificent could desire; our only care must be what to restore, what to destroy, what to build anew. A uniform process is all that is required to unite the dispersed materials; the expense is no part of the question, for in these days the want has but to be felt to be supplied. People are aware that though money may be trifled with, health may not, and expediency sinks in the consideration.

When, therefore, the question of metropolitan improvement has reached that state when men's minds are prepared for its consideration, the formation of a society for its furtherance cannot fail to be a successful means of accomplishing the object. The difficulties which might have arisen from such a plan, emanating from selfish purposes, are well met in the prospectus of the present society, which declares that the society is not formed to originate plans, or to advocate particular views, but to discuss their merits and to draw the attention of the legislature to the subject. Supported as the Metropolitan Improvement Society already is, by many of those who have individually laboured with honour for the same purposes, it must have a moral weight which will powerfully contribute towards its success. The main objects which are to be kept in view are, first, the means of checking the mortality now reigning in over-crowded and ill-drained neighbourhoods; second, affording facilities for commercial intercourse; third, the suggestion of proper sites for churches, schools, and other public institutions, and for parks and public walks; and fourth, decoration or architectural embellishment. The means of consuming smoke is also noticed as a subject for inquiry, and generally all plans and suggestions which have a tendency to forward the general objects of the society. The consideration how the funds for this purpose can be best provided is of course a necessary part of the plan, but little difficulty is to be anticipated on that score, as tax of two-pence or three-pence in the pound will amply provide for all wants, and can meet with but few opponents. To our readers this society cannot be too strongly recommended, for independently of the smallness of the subscription, the self-interest they have in promoting its objects must be a sufficient stimulus for securing their adhesion; as, too, the society proposes to discuss any building or drainage bills, or others affecting the metropolis, it will become a powerful centre of attraction to all earnest for their own welfare and that of their profession.

To the originators of this society a great debt of gratitude is due, for its beneficial influence must be felt not only here, but in every great city in the English empire and the world.

IMPROVED PAPIER MACHE'.—The endless variety of architectural ornaments to which this material is now adopted, is well deserving the notice of the architect and every man of taste. Upon a recent visit to Mr. Bielefeld's manufactory in Wellington Street, Strand, we were much surprised to find the numerous and beautiful forms into which this material is now moulded; foliage, either Gothic, Grecian, Roman, Elizabethan, or Renaissance, is here developed in an endless variety of ornaments for mouldings, cornices, panels, ceilings picture frames, &c., from the most minute mouldings to the largest size, from paterae of an inch diameter to the centre flower of 66 inches diameter. Capitals of the Ionic order, and Corinthian, from the examples of Jupiter Stator, monument of Lysicrates, the Tivoli and Temple of the Winds, besides numerous capitals of the Gothic, Elizabethan, and other styles. The frames for pictures and chimney glasses are of the most elaborate workmanship; one that we saw in the Show Room, 6 feet by 4 feet, was adorned with foliage of the most beautiful description, with Cupids in alto-relievo, copied from a fine specimen of old oak carving. We might continue on detailing the numerous works collected in this store-house of ornament, and fill our Journal; we therefore must recommend the architect to visit the show-rooms and judge for himself.

PEN AND PENCIL SKETCHES IN POITIERS AND
ANGOULEME: WITH SOME REMARKS ON EARLY
ARCHITECTURE.

By GEORGE GODWIN JUN., F.R.S., &c.

(Continued from page 71.)

Chapter 2.

Fig. 4.

THE western front of Notre Dame la Grande of Poitiers, represented by the above engraving, (Fig. 4.) is a most interesting example of a class of buildings peculiar to this part of France. The possession of stone easy to work, the greater influence of Byzantine taste, as well as other circumstances, have produced a marked difference in the architecture of various provinces, although proceeding from the same type: thus while we find in Normandy buildings of simple severity, adorned exteriorly with little more than zig-zags and rudely-sculptured corbels, we have here façades elaborately sculptured from the ground to the summit, presenting not merely highly-enriched and often very elegant capitals, borders, and scrolls, but multitudinous figures in all imaginable positions, and in very high relief. The absence of the western towers, too, in the structures we are now speaking of, constitutes another marked difference from the Norman buildings.

The date of the erection of Notre Dame is probably at the end of the 11th or beginning of the 12th century; but the entrance front is unquestionably more recent. This part of the building, which is bounded by clusters of columns supporting two small circular turrets with conical stone roofs, is divided into three distinct stages by enriched cornices, and terminates in a broken pediment or gable, (so to speak,) which is also divided horizontally into two compartments. The entrance doorway, which is recessed, is semicircular in the upper part, as are the arcades above containing figures; but the blank opening on either side of it has a pointed head with two small semicircular arches beneath it. The spandrels beneath the first cornice and corbels contain a series of bas reliefs, representing on the left-hand side of the spectator Adam and Eve, Nebuchadnezzar, some of the prophets, and an angel announcing to Mary the dignity of her coming child; and on the other side the meeting of the Virgin and Elizabeth, and the birth of the Saviour. Over the doorway is a circular-headed window, with a canopied niche on either side, which is an interpolation of later times. The figures in the arcades represent the apostles and two bishops. The lower part of the gable is inlaid with a series of small circular discs, and the upper part of it with squares placed diagonally:

in the centre of the two parts is sculptured a large *vescica piscis*, containing a figure of Christ and symbols of the four evangelists, namely the bull, the angel, the eagle and the lion.

The veneration in which the form called *vescica piscis* appears to have been held, and its constant occurrence in ancient buildings, have afforded matter for much disquisition. The early Christians symbolized our Saviour by the form of a fish, because, as has been supposed, the initial letters of Christ's name and titles form the Greek ΙΧΘΥΣ (fish): moreover, according to Tertullian, who wrote in the second century, they called themselves *Pisciculi*, considering that the Christian life commenced in the waters of baptism.* The fish itself was accordingly sculptured for decoration, but seems to have been afterwards superseded by the fish-shaped compartment formed by the intersection of two equal circles, in some cases rounded at one end. In England this is found in a variety of positions and of various dimensions, both in stone and on painted glass: it is to be seen over many doorways, enclosing the figure of Christ,—as for example, in the south porch at Malmsbury Abbey Church, (represented in the annexed sketch, Fig. 5,) at Barfreston, and at Rochester Cathedral. Medallions

Fig. 5.

of this shape, containing sculptured figures, occur frequently round the doorways of Anglo-Norman buildings, as at Malmsbury; and windows of this outline are found at Romsey Church, Hampshire, Beverley Minster, Yorkshire, Salisbury Cathedral, and elsewhere. In York Cathedral a boss in the groining presents the *vescica piscis* enclosing a figure of the Virgin. The rose window at the south end of the south transept of Lincoln Cathedral is formed by the tracery into a *double vescica*; while (stepping from England into Germany,) over the west door of the Church of St. Cunibert, Cologne, a *half vescica* occurs, enclosing the lamb. The seals of most religious bodies, as well as of individuals, were of this shape, and continue in many cases to be so; it was likewise delineated constantly on ancient tiles, as may be seen in many of our old churches: some antiquaries have even attributed the whole origin of the pointed style of architecture to the use of this form. Some writers have applied the term *vescica piscis* to two circles intersecting each other in the centre, and not to the form produced at their intersection, and have asserted the influence of this symbol over the plans of early edifices. In many instances, certainly, the prevalence of

* "Nos pisciculi secundum ΙΧΘΥΣ nostrum Jesum Christum, in aqua nascimur." *Tertul. de Bapt.*, cap. 1. Optatus, who wrote in the fourth century, throws some light on this passage thus:—"Cujus piscis nomen secundum appellationem Græcam in uno nomine per singulas literas turbam sanctorum nominum continet ΙΧΘΥΣ, quod est Latine Jesus Christus, Dei Filius, Salvator." He refers also in a mystical manner to the fish recorded in the book of Tobit. An annotator upon Optatus refers to Clemens Alexandrinus for confirmation of his use of ΙΧΘΥΣ; but on examination of the context, it does not seem that Clemens at all intended to allude to it. A reference however, to St. Augustine is more satisfactory. In his work *De Civitate Dei*, lib. 18, cap. 23, he writes, "Horum autem Græcorum quinque verborum, quæ sunt 'Ιησους Χριστος, Θεου υιος, Σωτης, quod est Latine, Jesus Christus, Dei Filius, Salvator, si primas literas jungas erit ΙΧΘΥΣ, id est, piscis, in quo nomine mystice intelligitur Christus, eo quod in hujus mortalitatis abyssos, velut in aquarum profunditate vivus, hoc est, sine peccato esse poterit." The origin of this species of acrostic, according to him, is in the Sibylline verses, some of which seem really to have been prophetic of our Saviour (being probably grounded upon the Jewish prophecies, which had gradually after the Captivity found their way among the heathens), while some were clearly interpolated by the early Christians, who seem, even in those days to have given way occasionally to the temptation presented by a pious fraud.

this form is strikingly apparent; but whether this may not result from the dependence of the early architects on geometrical proportion and fixed principles, (equally in the middle ages as in classic times,) I will not inquire. The symbolism of ancient architecture is an enticing but a dangerous subject to enter upon.*

In the towns under notice, the *vesica piscis* occurs prominently in the gables of the churches, as it does also at times in the painted adornments.† In one instance, I found it sculptured on the capital of a column, namely, at the entrance doorway in the tower of St. Porchaire, Poitiers; and of this, the annexed sketch, Fig. 6, gives a slight

Fig. 6.

representation.‡ The French writers, with some few exceptions, do not recognise this form in their descriptions as anything more than "a sort of oval," or "a glory." M. Didron, in an erudite and interesting paper on the nimbus, printed in the "*Revue Générale de l'Architecture*,"§ says the term *vesica piscis* should be repudiated by all for its grossness. M. Didron continues, "it was invented by the English antiquaries, who use and abuse it abundantly. . . Moreover this denomination is false, for very often the glory has not the form which the term suggests. This glory has been also called the sacred oval, and the mystic almond; but the word mystic suggests a symbolic intention which may very reasonably be doubted: besides, frequently it is neither of an oval nor an almond shape; it is simply the glory of the whole body, as the nimbus is the glory of the head.|| The head is round, the nimbus is round; the upright body forms a lengthened oval, and the glory generally assumes a similar form. But when the body is seated, the oval is contracted to a circle. Sometimes it becomes a quatre-foil, so that the four prominent portions of the body, the head, the legs, and the two arms, have each their particular lobe or section of the nimbus."

* As an early example, though, of the practice of symbolic architecture, if it may be so termed, a passage in the 18th chapter of the 1st book of Kings occurs to me:—"And Elijah took twelve stones, according to the number of the tribes of the sons of Jacob, and with the stones he built an altar in the name of the Lord." This was about a thousand years before our era.

† Dallaway says of the *vesica piscis*, "In the earliest era of the masonic establishment, a geometrical figure or canon was adopted in all sacred buildings, which had an import hid from the vulgar. As it had a decided reference to the Christian religion, it might have been invented by the Church; but it has likewise an equal analogy with other mysteries professed by the first societies "of masons." • It may be traced from the church of St. John Lateran and old St. Peter's at Rome, to the church of Bath, one of the latest Gothic buildings of any consequence in England."

‡ The tower of the church of St. Porchaire, apparently of the end of the 11th century, is in character what we should term Norman. A very wide doorway occupies nearly the whole width of the tower between the buttresses. Above are three stories separated by ranges of sculptured corbels (mostly heads), and containing arched openings and columns. The recesses being deeply sunk, the columns large, and parts bold, the effect of this tower is very picturesque and striking.

§ A French periodical, conducted very ably by M. Cæsar Daly, which deserves to be better known in England than it is.

|| Mr. Hope thinks differently, even of the nimbus. He says, "The Pagan fashion of protecting the heads of deities, often, even in temples, exposed to the outer air, from the insults of birds, each by a metal discus, had by degrees so associated with that head-piece an idea of dignity, that the Christians adopted the form, in order to mark, even in painting, the character of saintship: thence the nimbus introduced over saints in the more ancient paintings and mosaics, so far from being intended to represent a mere aureole, or glory of intangible rays, emanating from the wearer himself, is only the representation of a solid platter of silver or gold, often adorned with scrolls foliage, gems, &c. fitting the skull."—*Hist. of Archit.* p. 173.

With the greatest respect for the opinion of M. Didron, I am unable at once to assent to this apparently clear and straightforward explanation. The constant recurrence of this particular form, any departure from it being apparently but the exception from a rule; the fact that in very many cases the *vesica piscis* encloses a sitting figure, and in others no figure at all; that the quatre-foils spoken of may actually be formed by one *vesica* crossing another; and its use for episcopal seals and for windows, as before alluded to, are all points that might be urged in objection. Touching the invention of the term *vesica piscis*, Mr. Kerich states that it is spoken of by Albert Dürer, in a work published in Paris at the commencement of the 16th century, as one perfectly well understood at that time.*

To return, however, from this digression, to Notre Dame of Poitiers. What has been said, aided by the engraving, will be sufficient to show that the entrance front of this building is a very extraordinary and striking work. There is hardly a square foot of surface that is not elaborately, and, in some cases, beautifully sculptured in very bold relief, the effect of which, when heightened by colours and gilding, (as it appears from traces was formerly the case,) must have been very extraordinary.† The south side of the building, which is partly exposed, presents simply a range of blank openings, formerly windows: these, with the exception of two immediately adjoining the west front, have semicircular heads; the two exceptions are slightly pointed. There is a central tower in three stories, (the two lower square, and the upper story circular,) covered with a conical roof, the stones whereof are formed into scales, as likewise are the stones composing the roof of the turrets in the entrance front before mentioned.

The interior consists of a nave and side aisles, (the latter being very narrow), choir, with semicircular termination, and attached chapels. The vaulting of the nave is wagon-headed, with plain horizontal bands passing from column to column; that of the aisles is groined. The arches which separate the nave and aisles are lofty, and go up to the springing of the vault, there being no clerestory or triforium: the whole is of massive yet elegant proportions. Some of the capitals, although for the most part plain, are sculptured with interlaced ornaments.‡

At the south-western extremity of the town is a church dedicated to St. Hilarius, one of the most eminent of the bishops of Poitiers, who lived in the fourth century, and was distinguished by his active opposition to the Arians.§ Clovis in the sixth century rebuilt a ruined chapel which had been erected over his tomb: this, in its turn, was destroyed by the Normans about the year 863, and the present church was built at the commencement of the 11th century, and consecrated in 1049. Originally it was much larger than it is now, and was divided by six ranges of columns into a nave, with three aisles on each side, covered by six cupolas. During the revolution the building fell greatly into decay; so much so, that when its repair was desired, a commission appointed for that purpose foolishly determined on destroying a great part of the original structure, instead of restoring it.

The building as now seen is accordingly much confused in arrangement, but presents, nevertheless, a striking interior. It is semicircular throughout, with a plain wagon-headed roof in part, the arches supporting which go up to the springing of it, without the interposition of triforium or clerestory. At the back of the high altar is a semicircular range of columns, with plain cushion-capitals, of lofty and elegant proportions. Some of the other columns in the church have capitals sculptured into representations of men and animals. The head of one arched opening outside the tower is cut on the face and the intrados, in imitation of an arch formed of three layers of billets of wood, a caprice on the part of the architect or the masons not common.

* *Archæologia*, Vol. XVI, p. 313.

† The whole width of this front is 57 feet. It may be mentioned, that the mortar joints are not large, but that the stones, where not decayed, fit closely together.

‡ The height of the vaulting in the nave is about 54 feet, that of the aisles about 36 feet. The whole length of the building inside is stated to be about 187 feet, and its width 44 feet.

§ He was the author of the *Te Deum* still used.

Among the eminent individuals of whom Poitiers was in old time the residence, the memory of none is more respected than that of *Ste. Radégonde*, wife of *Clotaire I*, who, abandoning the pleasures of the world and her high position, established herself in Poitiers, and founded there, about the middle of the sixth century, an abbey, which took the name of *St. Croix*, from a relic of the true cross given to *Radégonde* by the emperor *Justinian*. Near the monastery, but beyond the walls of the city, she built a church for the burial of the sisterhood. This is supposed to have been destroyed by the Normans in 1084, and rebuilt at the expiration of the same century.

The church, as it now remains, is noticeable for the large span of the vaulting over the nave, which has no aisles. The structure is chiefly of semicircular work, and has a lofty arcade against the side walls of the nave, similar to that already mentioned in the cathedral. The choir has an aisle on either side of it, with a semicircular absis and two small chapels. Beneath the high altar is a chapel, containing

the remains of *Radégonde*, in a black merble tomb of evident antiquity. Externally the church has a square tower at the western end, the upper story of which is octagon. Against the north side of the tower is a circular turret with a conical roof, which renders the general effect of the tower picturesque. The walls of this building, both inside and out, are literally covered with masons' marks, in some cases precisely similar to those about the cathedral.

The only other church in Poitiers is that of *Montierneuf*, which was commenced in 1076, by *Guillaume Guy Geoffroy*, Count of Poitiers, but was not completed till twenty years afterwards: the choir was afterwards rebuilt. An attempt has been made to render the whole of the interior classical, by sculpturing an egg and tongue around the capitals of the columns, and other unwise contrivances. On the roof outside are two turrets, with conical roofs and arched openings, similar to those at *Notre Dame la Grande*, but smaller and more rude.

ROBERT B. DOCKRAY'S SELF-ACTING RAILWAY SIGNAL.

Fig. 1.

Fig. 3.

Fig. 4.

Fig. 5.

The intention of this signal is to notify to an approaching engine-driver, that a preceding train has passed any given point upon a railway at a certain interval of time before him. It is proposed to fix it at the entrances to tunnels, in deep cuttings, where the curvature of the road obstructs the sight, or in any other position where it may be thought desirable to warn the engine-drivers, without the expence of having policemen in constant attendance to give the necessary signals.

DESCRIPTION OF THE DRAWINGS.

Fig. 1, is a section through the signal, and one line of railway.

Fig. 2, is a section and elevation taken through the connecting rod, and parallel with the line.

Fig. 3, is an elevation of the disc and lamp head, showing the face of the clock, figured 5, 10, and 15 minutes.

Figs. 4 and 5 are sections of the lamp head.

In all cases the same letters refer to the same parts:—*a*, in section at Fig. 1, and in elevation at Fig. 2, is an inclined plane, over which a friction roller, fixed to the engine, is intended to pass, and in so doing, depress it to the level of the rail; it is attached to the connecting rod *c* by means of the bell-crank *b*; *d* is a rack fixed to the rod *c*, giving a quarter turn to the disc *i*, through the pinion *f*, the crank *g*, and the vertical shaft *h*; *k* is a double crank fixed to the end of the rod *c*, one arm of this crank carries the balance weight *l*, the other arm lifts the piston *r* in the cylinder *s*; by means of the connecting rod *n*, the lever *m*, and the vertical piston rod *p*, the upper part of this rod communicates motion to the clock, shown to a larger scale at Figs. 4 and 5, where *p* is the piston rod having a rack working into the teeth of the wheel *q*, upon the axis of which the fingers of the clock are carried; the cylinder *s* is open at the top, and has a valve *t* opening inwards to admit air under the piston during its ascent, and a stopcock *u* regulating the egress of the air from under the piston, which, descending by its weight, drives the air out before it, with a velocity proportioned to the area of the aperture, and thus by opening or closing the stopcock, the time for the revolution of the hands of the clock can be increased or diminished at pleasure; the piston, on descending to the bottom of the cylinder, lifts the catch *e* out of the notch provided for it in the rod *c*, and releases the balance weight *l*.

For the night signals, the clock, having a transparent white face, is illuminated by the lamp and reflector *x*, Fig. 5; the vertical shaft *h*,

which carries the day signal *i*, also carries a disc of red glass, *y*, fixed within the lamp, and between the clock face and the light, and also in the same vertical plane as the day disc; consequently, when the quarter turn is given to the shaft *h*, the red glass is turned before the light, and the clock face is illuminated red, and thus calls the attention of the engine driver to the clock face.

Mode of Action.—The inclined plane *a*, in descending, draws the rod *c* forward, and lifts the weight *l*; the catch *e* descends into its notch, and retains them in this position; in the mean time the red disc *i* has been turned by the rack *d* so as to be visible from the line, the piston *r* has been lifted to the top of the cylinder, and descending by its weight, communicates motion to the clock; on reaching the bottom of the cylinder, it lifts up the catch *e*, which, rising out of the notch in the rod *c*, releases the balance weight *l*, which, by its gravity, brings the different parts of the apparatus into their first position, and the signal is ready for the passage of another train.

By these means the engine-driver, on passing the signal, and looking at the clock, can tell by night or by day how many minutes have elapsed since the passing of the previous train, and either stop until the time for the revolution of the hand has expired, or regulate his speed, according to his instructions.

The only attention the signal requires is the cleaning and lighting of the lamp, which might be done by one of the plate-layers, who are always upon the road.

TREWHITT'S PATENT FOR DISCONNECTING THE PADDLE-WHEELS OF STEAM VESSELS.

SIR—Observing a notice in your Journal for February on "Trewitt's patent method of disconnecting the Paddle-wheels of Steam Vessels," in which there are several inaccuracies, we beg the favour of your inserting the enclosed, which is a correct representation and description of the apparatus applied by us to H.M. steamer *Kite*.

Engine Manufactory, New Road,
Feb. 11, 1842.

We are, Sir,
Your obedient Servants,
BRAITHWAITE, MILNER & Co.

Front view and section of crank.

Side view.

EXPLANATION OF THE DRAWING.

A. The Paddle Shaft. B. A cast iron Disc keyed thereon. C. A wrought iron Strap surrounding the Disc, lined with brass. D. A brass Cushion. E. A tightening key for producing friction, by bringing the Cushion in contact with the Disc. F. The brass lining the wrought iron Strap, excepting that portion occupied by the Cushion. *fff*. Screws by which the brass lining is held to the Strap.

A few blows of a hammer on the key E will connect or disconnect the Paddle-shaft, even when the engines are at full speed.

REVIEWS.

The Present State of Ecclesiastical Architecture in England. Dublin Review: No. XXIII.

THE satisfaction we feel at meeting with an architectural paper of such very unusual extent—for its length exceeds a hundred pages, with numerous foot notes in small type, and illustrated, besides, with 17 plates—our satisfaction, we say, is greatly abated, at finding so very large a portion of it devoted to non-architectural matters, and, in fact, the subject itself made a stalking-horse to ecclesiastical controversy—to lamentations for “the desecrated state of England’s churches after the great schism of the sixteenth century,” intermixed with such occasional specimens of holy hatred and pious execration as that where the writer denounces “the *blasting influence* of Protestantism and Paganism combined!” From this last somewhat startling expression the tone and spirit of the article may easily be inferred; and though there is occasionally a show of candour, in complimenting those who have evinced a desire to restore, to a certain extent, some of the forms that have fallen into disuse, into our church-service, we cannot help looking upon it as no better than cajolery. The interest pretended to be felt can hardly be sincere, otherwise than as it proceeds perhaps from the latent hope that the return to some ancient usages will proceed, step by step, till all shall have been restored; and, with those external customs and usages, creeds and points of doctrine likewise. Sincere, however, or not, it certainly does appear to us, that the concern here expressed in regard to our protestant churches and their architecture, is somewhat inconsistent—not to call it officious—somewhat too much akin to the concern we may suppose the Bishop of London to give himself in regard to the synagogues and Quakers’ meeting-houses, and the forms and regulations adopted in the various sectarian places of worship in his diocese. But we are now falling into the error we have just animadverted upon as pervading the article in the Dublin Review, and therefore quit such remarks as those just made, for others of more immediate interest to our readers.

We are so very far from being opposed to reform in our present system of church architecture, that we consider it loudly called for, since, with comparatively few exceptions, the numerous churches erected in this country of late years are the very reverse of satisfactory, being stamped not only by the meanness occasioned by injudicious parsimony and mistaken economy, but by downright vulgarity and pertness of character. We are aware that architects will say the fault does not at all rest with them, since they do as much as the funds afforded them will allow. We must, however, plainly tell them that, as often as not, they do not accomplish *so much* as they might do, merely because they aim at *so very much more* than can possibly be accomplished under the respective circumstances. If a design answers, as far as name goes, to some particular style, by the forms adopted for windows, and a few other features of that kind, no attention is paid to the genius of the style itself, or to such treatment of it as is requisite to keep up its proper character. Seldom, too, is any regard paid to the exigencies of the particular case, for many new churches look as if the designs for them had been merely copied, with some trivial alteration, from those pattern-books of them published for the benefit of country architects, and brought down to the taste of parish committees. Or, does a design happen to be objected to, as too expensive, or as otherwise requiring some curtailment, a very easy remedy is resorted to, namely, that of paring it down, or lopping off from it, by which process it must of course become *simplified*; and a most simple-looking affair it generally turns out, looking very much like a cock that has been stripped of all its feathers.

Now the fact is, nearly all our old village churches rise up in judgment against modern church architects—at least the majority of them. Such structures may be homely, but they are not vulgar; they may be uncouth, they may be even mean, may be rude enough both in construction and material, but they are never vulgar, except, indeed, where they have undergone the process of “*beautifying*” to such extent, that their original and proper character has been destroyed. It is unquestionably true that, for the impression they make both upon the eye and the mind, buildings of the class alluded to are more or less indebted to the effects of time. Equally true is it, that it is beyond the power of the architect to create antiquity, and confer on his buildings, in addition to the venerable appearance, the accumulated associations derived from it. Still, apart from that element of their character, there are others which recommend the class of churches alluded to, if not exactly as models, as *studies*, at the present day, which, if properly turned to account would go far towards correcting that insipid triviality, and that vulgarity, which, together with a certain uncomfortable look

of starvation and flauntingness combined, are the besetting sins of most of our modern *soi-disant* Gothic churches, and not least of all those which, because they are stuck full of naked lancet-holes, assume to themselves the title of the early English style, whereas they have in fact nothing whatever of the character of that style; nothing of the feeling belonging to it, nor aught of that which gives it value. One exceedingly great fault in the church architecture of the present day arises from the meagreness and formality produced by a number of uniform apertures, stuck so closely together as not only to destroy all repose, but produce a very disagreeable appearance of want of substance and solidity. It is true, in the later perpendicular style the proportion of the apertures to the solids is very much greater—so much so, that many structures in it may be compared to lanterns, being in fact nearly all window; but then the character is of a very peculiar kind, the whole forming a consistent design of elaborate screen-work, as it were, which would almost admit of being perforated throughout. Instead of being mere gaps, the windows themselves are filled with screen-work, with numerous mullions, transoms, and tracery, so as to combine the appearance of strength with that of richness. Where, on the contrary, the windows are so far from contributing at all to decoration that they are little more than so many blank surfaces of glass, with scarcely any external moulding or finish to the apertures—as is the case with not a few of our modern-antiques, or pseudo-early-English—they ought to be as few, in other words as wide apart, as possible.

If very few architects seem to understand simplicity, there are as few who seem to be able to appreciate the value of sobriety in design; or we might suppose that sobriety is so exceedingly expensive a quality that they cannot afford to make use of it, except on very rare occasions. Be that as it may, it is certain that much of what is more or less unsatisfactory, if not decidedly reprehensible, in our recent church architecture, arises from a want of attention to sobriety in composition. Hence moderate-sized churches are made to look like miniature editions of large ones; owing to which preposterous ambition, instead of gaining in importance, they become more insignificant in appearance than smaller ones with the proper character belonging to them as such. While it does not absolutely exclude a higher degree of decoration than usual, sobriety requires that the decoration itself should be applied somewhat sparingly; that the features of the composition should be few, but carefully studied, and individually satisfactory and capable of bearing the test of examination. Richness there may be, but sobriety and trumpery are totally irreconcilable with each other.

For calling attention to this point we may very well be excused, since it is one that is oftener than not completely overlooked; though were it attended to, we should behold fewer of the miserable minikin abortions and spawnings of church architecture that now meet our eyes. Intimately connected with the disregard of sobriety, there is another very prevalent fault in designs of the class alluded to, namely, excessive meagreness and monotony of composition, quite the reverse of what is observable in buildings that are or ought to be looked to as examples, or at least, as studies. Assuredly it is not a little inconsistent, that while so much stress is laid upon style, and so much importance attached to precedent, the character of the one and the authority of the other should be utterly disregarded—if not universally, far too frequently—in general design or composition. Our modern Gothic churches have for the most part an exceedingly offensive box-like appearance, without anything to break the outline, either horizontally or on the plan; without anything to take off from the flatness and insipidity of the elevations, to produce effect of light and shade, and contrast of lines in perspective. Consequently, unless the design be of very superior quality as to beauty of detail and execution, the whole structure is apt to look deplorably naked and bald.

As we write not to compliment or flatter, but if possible, to instruct and improve, we must speak out plainly, and tell the profession that, if we may judge from their essays in it, they have yet very much to learn in regard to the proper *treatment* of Gothic architecture, and, we might perhaps add, of Grecian also. It may be that they are frequently thwarted by the obstinacy and ignorance of other persons—by that collective stupidity which calls itself a committee, and which insists upon a design being accommodated to its own notions and whims. On which side the fault rests, or whether it is to be shared between both, we pretend not to say; but we will say that if the character of Gothic architecture, or of any of the styles belonging to it, cannot be better kept up than it usually is when such style is applied to modern churches, it becomes a question whether it would not be better to repudiate it altogether, or at any rate to employ it only where circumstances allow of its being properly kept up in every respect.

For the interiors of churches as at present required to be laid out, the greatest possible extent of accommodation as to sitting room being

made the *sine quâ non* to which all other considerations must yield, the Gothic is not particularly well calculated, because it must be violated more or less, except when galleries can be dispensed with altogether, and open seats and stalls be substituted for pews. We do not blame architects for not accomplishing impossibilities; for if similarly blocked up and built up, the beauty of the finest Gothic interior would inevitably be greatly impaired, if not destroyed: but we regret that such style should be so applied, or rather misapplied, since even a tolerable semblance of it can hardly be kept up. For this last reason, perhaps, it is that generally no attempt whatever is made to keep it up at all; and we have seen churches in that style which, though tolerable enough on the outside, have been most intolerably bad within—without the slightest pretensions to style, without any sort of architectural beauty, and without any solemnity of character, unless dismalness and pauper-like meanness can be considered equivalent to solemnity. If, in addition to the rest, aisles also are to be blocked up by pews, they had better be omitted, since they certainly contribute nothing to architectural effect, and as little to commodiousness, those there seated not being in the very best situation for hearing distinctly.

It seems to us, that by employing the Gothic style—at least, as it is now employed—we inevitably force comparisons not very flattering to Protestantism in its relationship to art. It admits of no dispute that Catholicism is infinitely more favourable to architecture and the other arts. Its very character—its taste for religious parade, and pantomime, and pageantry, and processions, and for all the paraphernalia and pomp of devotion, render it pre-eminently picturesque and scenic—the religion for the artist, *quoad* artist; which unconditional admission on our part must satisfy both the Dublin Review and Mr. Pugin; for were we to express our sentiments of Catholicism as a religious system, and to be as free in our remarks as the writer in the Review is upon Protestantism, we should not satisfy them at all.

In regard to the symbolical character of church architecture, to which so much importance is attached by the Reviewer, we shall merely observe that it appears to us very fanciful—historically interesting, perhaps, as showing the religious spirit of former ages, but not at all likely to be revived now, it being, in fact, totally disregarded in Catholic countries. Indeed, though they do not care even to hint as much, many recent specimens of ecclesiastical architecture, both in France and Italy, must scandalize Messrs. Pugin & Co. not a little. Not to mention others, La Madeleine at Paris, and Canova's church at Possagno, must appear to them as awfully heterodox—manifestations of the "blasting influence of Paganism," *without* Protestantism. The Reviewer, however, does speak of "the Pagan courts of the Medici;" and while he was casting reflections upon the questionable taste which attaches such high value to the Elgin marbles, he might have added a few upon that which has converted the sovereign abode of St. Peter's successor into a Pantheon of Pagan divinities, and a storehouse of heathen mythology: but those scandals were of course in the wallet behind his back.

Dismissing the rest of the article without further comment—for if not so already, the Review itself will doubtless be in the hands of most of our readers, ere long—we now turn to the plates, which, with one exception, are representations of buildings erected by Mr. Pugin. And hardly can he be accused of having flattered them, or attempting to do so, since they are drawn and etched in a most affectedly rude manner; and some of the subjects are rendered still more uncouth by being shown in bird's-eye perspective—a most unnatural and unpictorial mode of representation. It is, perhaps, chiefly owing to these circumstances combined, that the illustrations are so little prepossessing, except to those who may admire them because they studiously imitate all the defects of old engravings at a time when architectural delineation was in its infancy. Spirit and freedom are very desirable, but accuracy of form is an indispensable requisite in drawings whose value depends upon their truth as graphic descriptions, and that such accuracy is not incompatible with artist-like feeling the publications of the elder Pugin sufficiently convince us; in this respect, therefore, the son appears to have degenerated from the sire. Granting, however, that as etchings they may be called spirited, some of the designs themselves appear to us not a little insipid, and to be very deficient in that spirit which the style derives from well expressed detail. Such character there may be in the buildings themselves, yet so far from being shown, it is not even indicated here. On the contrary, in some of the subjects, for instance St. John's Hospital, Alton, and the bishop's residence, Birmingham, it appears to be wanting altogether; there being a good deal in them that looks scarcely of better quality than those spurious "Gothicisms" which Mr. Pugin himself has so loudly reprobated. This is particularly the case with regard to the bishop's house, which, besides being remarkably *queer* and uncouth, has the appearance of being an old structure altered and patched up and

huddled up, from time to time, without the slightest attention to consistency of design. So far, indeed, it may pass for being picturesque; yet Mr. Pugin must surely be aware that though such kind of picturesqueness is agreeable enough in itself, where it has really been the growth of time and successive changes, and where beauty is out of the question, it becomes little better than an offensive piece of affectation when perpetrated for the nonce, and to the extent in which he has indulged in it. Difficult as it may be to effect, in design we look for picturesque quality combined with architectural unity of expression, if not always with perfect regularity. In his horror of the frigid formality and smirking pertness of the carpenters' Gothic school of design, Mr. Pugin has run quite into the contrary extreme: while the former, therefore, are clearly in the wrong, he himself is far from being yet quite in the right. He is too apt to give us architectural farragos, instead of designs: he succeeds in individual features and parts, but he is by no means happy in composition. His reverence for precedent causes the antiquary to prevail in him over the artist to such a degree, that he may be compared to the precedent-loving Chinese tailor, who, being employed to make a new coat, copied every patch upon the old one sent him as a pattern.

Memoir on the Practicability of shortening the duration of Voyages by the adaptation of Auxiliary Steam Power to Sailing Vessels. By SAMUEL SEAWARD, F.R.S., M. Inst. C.E. From the Transactions of the Institution of Civil Engineers. Part V, Vol. 3, 1841.

THE fearful expense which has been found to attend the extension of steam navigation to voyages of extraordinary length appears to constitute an insuperable obstacle in the present state of the steam engine to the beneficial establishment of lines of uninterrupted steam intercourse between distant continents. The imperfect success which has attended the development of the several enterprises which had for their object the maintenance of a steam communication between Great Britain and New York, is a proof of the difficulties which wait upon the performance of long steam voyages, and furnishes a lesson which will not be readily forgotten by future speculators. The successive disappearance of the *Sirius*, *Royal William*, *Liverpool*, *United States*, *British Queen*, &c., from the Atlantic station, proclaims with a voice as authoritative as that of a messenger from heaven, that the Atlantic enterprise has been a failure, and that a perseverance in its prosecution, *under the same circumstances* which drove those vessels from the field, can only add energy to ruin and flagrancy to guilt.

For several years past the project has been in contemplation to adapt steam power to sailing vessels, in such a manner that it may be used or discontinued at pleasure, and it is the object of the author of the work before us, to recommend the extended adoption of steam power in sailing ships, as being productive of the most prominent of the benefits which steam navigation confers, without entailing any serious expense for the maintenance of its operation. A good ship, when impelled by a favourable wind, will realize a velocity which few steam vessels are able to surpass, and it is only in calms, or when the wind is adverse, that the peculiar powers of a steam vessel are productive of benefit. It becomes a question, then, whether it would not be advantageous to so adapt steam power to sailing ships as to be only used in calms, or in adverse circumstances of wind and water.

In order to form any comparative estimate of the benefits of this proposed application of steam power, it is necessary to refer to the circumstances which attend the voyages of sailing ships and of regular steamers upon the open sea. In some of the lines of intercommunication between distant countries, vessels are exposed to strong periodical winds or protracted calms, whilst other lines are distinguished by winds which sweep across the ocean in one direction for nearly the whole year. In calms such as those that prevail about the line, and by which vessels on the route to India are often for a long period detained, a small proportion of steam power might be most beneficially employed in transporting the vessel from the region swept by the current of wind which flows from the pole towards the equator, into the locality of those land and sea breezes which enable the vessel to continue her voyage; but the same proportion of steam power would be perfectly unserviceable in propelling a properly rigged ship against a strong adverse wind. For such a service a proportion of power to tonnage similar to that observed in our fastest steamers is indispensable, and it is only therefore in voyages where calms are likely to be met with that the adaptation of auxiliary steam power to sailing ships can be productive of benefit. Upon the superior economy of vessels supplied with auxiliary steam power, Mr. Seaward makes several very sensible observations:—

"A most material circumstance affecting the utility and economy of steam vessels of great power, is the space necessarily occupied by the engines and the supply of coals, which are found to require three-fourths of the whole area below deck, leaving only one quarter for the stowage of cargo; and that, owing to the great weight of the former, must principally consist of measurement goods. Thus the "President" and the "British Queen," although of 2000 tons register, have never been able to carry more than 500 tons of measurement goods as freight.

"From a due consideration of these features of the question, with respect to the expediency of employing large steam vessels (and it is believed that few practical men will dispute the facts by which they are developed), it is evident that the attempt to perform voyages of lengthened duration by the power of steam alone must, in the present state of engineering science, be attended with an expense wholly disproportionate to the profits."

"The present state, therefore, of steam navigation is evidently altogether inadequate to meet the large and daily increasing demands of commerce; and in this respect, as far as maritime navigation (as contra-distinguished from river and coast navigation,) is concerned, steam must be considered to be in its infancy, for the communication by this means with our own or with foreign distant colonies—India, via the Cape of Good Hope—the West Indies—the Pacific Ocean—Australia—the Brazils, and other highly productive countries, is at present impracticable to any extent, as the facts hereafter stated will more distinctly show."

"Before entering upon the details of this scheme, either as regards its past success in the partial and limited application which it has hitherto received, or as to its future adaptation, it may be desirable to describe the class of sailing vessels to which auxiliary steam may be regarded as an applicable power, and where its employment may be expected to be attended with success; and here it must be observed, that commercial and not scientific success is the result looked to, for nothing can be considered successful in a commercial point of view, to which a fair profit upon the capital employed does not attach."

The definition of the term "success" here given might be looked upon as unnecessary, had we not before us the remembrance of the strange perversion of the plainest language, during the discussion of the Atlantic steam enterprise. In that case success was regarded as synonymous with practicability.

Mr. Seaward informs us that auxiliary steam power is beneficially applicable to all vessels, from 400 tons upwards, and that the proportion of one horse power to 25 tons will propel a vessel in a calm at the rate of 5 knots per hour. He then institutes a comparison between the time occupied by the ship "Vernon," fitted with auxiliary steam power, on her voyage from London to Calcutta, and that of the steam ship "India," which performed the same voyage about the same period. The expenses attendant upon the employment of auxiliary steam power in the "Vernon" during this voyage are stated to have been £600; whilst the expenses attendant upon the "India" for the same period are estimated at £4293, showing an excess of expenditure over that of the "Vernon" of £3693. The comparative rate of the vessels in point of speed, as stated by Mr. Seaward, appears by no means favourable to the "India;" but, as we know the "India" to have been detained for a considerable period at the Cape by stress of weather, and as we conceive there are evidences of some slight prejudice against the "India," in consequence, we presume, of her being a Clyde-built vessel, we attach but little value to this part of the statement.

Mr. Seaward's memoir contains much important information, and manifests a familiar acquaintance with the subject of which he undertakes to speak, and the possession of a liberal share of good common sense. It is also well written, though we should have been better pleased with it had there been less straining after rhetorical decoration; a serious fault in any paper which professes to treat of practical and scientific subjects, especially when addressed, not to the herd of mechanical amateurs, or scientific cyphers, but to an association of able and practical men. Another fault which pervades the work, is the frequency of reference to, and of involved commendation of, the Messrs. Seaward's engineering performances. We hear a great deal too much of the excellencies of the "Gem" and the "Ruby," and we find those vessels and the "Brunswick," the latter a work also of Messrs. Seaward's and a comparative failure, associated with and obtaining the precedence over the "Eclipse," the "Blackwall," and the "Railway," vessels by which, in point of speed, they are entirely outstripped. Such preferences as these manifest an unbecoming partiality, as ill-judged as it is impotent; and are equally unworthy of those by whom such communications are accredited as of those by whom they are rendered.

In conclusion, Mr. Seaward observes that he has avoided all recondite calculations, with a view of meeting more effectually the objects

of practical men. He further informs us, that theoretical calculations upon such a subject as that he has undertaken to handle, however suited to the philosopher's study, are of little value to the practical engineer or ship builder; and he quotes the language of the late President of the Institution of Civil Engineers, to the effect that, what is wanted for that society is the development of that knowledge which is founded upon practical experience. From this intimation we might infer that, in the opinion of this gentleman, science is incapable of rendering any aid to the practical mechanist, but that he would be prepared to go into the most recondite computations, were such a course desirable. In reference to the first allegation, it is only necessary to observe that, in the development of that knowledge which is founded upon practical experience, science is the most efficient instrument; in proof of which fact, we might refer to the extraordinary development the arts have experienced since their progress has been aided by the light of science, as compared with their stationary condition when they were merely empirical. As regards the second implied allegation, namely, that Mr. Seaward would be prepared to enter into extremely recondite calculations respecting the subject of his memoir, except for the weighty reason he has given, we can only admire the discretion which dictated so much forbearance. If it be Mr. Seaward's desire to maintain his reputation for profundity, he will best accomplish his object by avoiding all attempted manifestation of it. The only attempt of this description in the memoir before us is in the 4th page, where we are told that "the employment of a quadruple amount of steam power would not double the speed, although in theory this is assumed to be the fact." By whose theory is this assumption made? We presume that it must be of Mr. Seaward's own fabrication, and his exclusive property, it being the theory of other engineers that the resistance increases as the square of the velocity, and the power necessary to overcome that resistance, as the cube of the velocity. And the reason is obvious. If the power be doubled, the resistance is quadrupled; the force of the engine, therefore, to overcome this resistance, must be quadrupled also, and must act with a double speed. In other words, when the speed is doubled, the power requisite to maintain that speed has to be increased eight times instead of four times, as by the theory of Mr. Seaward.

A Treatise on the Application of Marine Surveying and Hydrometry to the practice of Civil Engineering. By DAVID STEVENSON, Civil Engineer. Adam and Charles Black, Edinburgh, 1842.

THE author here treats on a branch of surveying which has always been very imperfectly handled in works professing to convey information on this subject. The quaint and pithy directions of old writers, when they come to show the manner of surveying the coasts of harbours and rivers, will seldom fail to elicit a smile from the professional surveyor, at the idea that such directions would ever enable any one to perform what they are intended to teach; and scarcely less will he be moved by a mingled feeling of pity and ridicule for any unfortunate would-be surveyor, who, deeply read in the mystic lore of some ancient authority, should sally forth, in all confidence, to the task of performing a difficult river or harbour survey. Were it not that the practice and the knowledge of surveying are confined to a comparatively small number of persons, and that, consequently, errors which are made in surveys, and bungling, roundabout ways of proceeding are not often observed, we should undoubtedly have evidence enough to prove the necessity of practical information on a subject of such importance. If we could lay bare the secret trembling anxieties, the harassing emotions, the suppressed fears and doubts on the ultimate success and accuracy of his work, which torture the young surveyor in his hours of arduous application, whether in the field, poring over his theodolite and the hieroglyphics of his field-book, or in the house, straining over the net-work of his survey, as by slow degrees he develops it on the paper, we should even feel that a boon is conferred on humanity by a production which reduces to order and simplicity the details of a task calculated to puzzle, in no small degree, the ardent hasty brain of a youthful student. We therefore hail the book before us, judging from its title alone, and supposing it to have any merit at all, as a welcome accession to the engineer's library; our expectations also, on a first glance, were not diminished when we recognized its author to be the same Mr. Stevenson who favoured the profession not long since with an instructive work on the Civil Engineering of North America. Mr. Stevenson also boasts of a name not less celebrated in Scotland than that of his namesake in England, the

father of Mr. David Stevenson being universally known as the engineer of the Bell Rock Light House, and many other important works.

On attentively examining this book, we find that our expectations have been amply realized—we find it to be the production of one who thoroughly understanding the subject on which he writes, falters not, hesitates not, shrinks not from writing freely for fear of exposing his ignorance, resorts to no paltry expedients for filling up his book with mere words enveloping ideas like needles in hay; but who, in a clear, lucid, easy, and familiar style describes the manner of conducting the survey of a river or harbour, from beginning to end. The first two chapters are devoted to triangulation, and to the choice and measurement of a base line. It seems from these that the author adopts the method of connecting the two banks of the river by a series of angles taken from each station. The stations are at short distances from each other, and the construction lines of the survey change their direction at every station. Thus no line along the banks of the river is longer than the distance between two of the principal stations; and thus, when the construction lines are laid down, they form a series of triangles erected on each base from station to station, and having their vertices in opposite stations on the other side of the river. It is well known to most of our readers, that there are various methods of arranging the construction lines in surveying; and the one which is most strictly correct in a geometrical sense is undoubtedly that in which the whole work is enclosed by some large triangle, or at least entirely intersected by one or more straight lines, on which triangles are constructed as large as the extent of the work may require. The beautiful accuracy with which all the parts of a survey executed in this manner fit into each other; the strict tying of the work together; the admirable system of proofs and checks afforded; and the distribution of minute error arising from imperfect chaining, while any error of consequence is at once discovered at the precise spot where it occasions distortion;—all point out the method of surveying within long construction lines as the very best that can be adopted for all ordinary surveys of land. But in the case of rivers and coasts there are many practical objections to this method, arising from the difficulty of measuring long straight lines on the shore or margin sufficiently near the water to furnish the necessary offsets, and from the impracticability of measuring the numerous lines which would be required across the river, or which would be required to extend out to sea, supposing the system followed in the survey of a single line of coast. Hence in marine surveys the necessity of employing the theodolite or some other instrument for measuring angles is universally admitted; and this point being settled, the next consideration is that of determining the form and position of the series of triangles which, depending on each other and constructed in the manner of a continuous net or framework, constitute the basis for finding the main points and filling up the whole detail of the survey. The two first chapters afford some useful practical information, as to the best method of observing the angles and constructing these important lines.

The third chapter is devoted to tide observations, the author strongly insisting on the importance of these being correctly made at many different points, in consequence of the irregular level assumed by the tide wave at different parts of its course up the river. Some very curious and important details are given in this and the following chapter on soundings, relative to the inclined surface presented by the water in tidal rivers at different times of the tide. Thus in the river Lune, the current of which runs from Lancaster to Glasson, the level of low water during a spring tide was found to be 11 ft. lower at the latter place than at Lancaster. Also at the same instant of time, when it was low water at Lancaster, the level of water at Glasson was 4 ft. 4 in. above low water mark at Lancaster. On the river Dee the level of low water mark at Flint was 7½ ft. below the low water mark of the same tide at Connah's Quay, only 2½ miles higher up the river. And at the moment of low water at Connah's Quay, the water at Flint was 5½ ft. above low water mark at Connah's Quay. These are only a few examples of the irregularity of level presented by the surface of water in tide rivers: in the course of the book there are many such examples, extending through both spring and neap tides. They prove in the most decided manner—1st. that it is an egregious error to assume the low water mark at different points on the same river to be on the same level; and, 2nd. that it is almost equally erroneous to suppose that at any given instant of time the level of water in a river is the same at two distant points. A difference of level, also, prevails in the high water mark of the rivers Dee, Lune, and Forth, from all of which actual observations are detailed; but this difference is not to such an extent as that in the level of the low water marks, although in other rivers it is possible that the line drawn through the high water marks of the same tide may be as much inclined as the line drawn through the low water marks. We have not unfrequently seen cases of disputed levelling, only in consequence of erroneous ideas as to the contem-

poraneous level of tide water, and as to the level of high and low water mark at different points of a river; and doubts have often been thrown, in consequence, upon the accuracy of a section taken across a district of country, from one point of a river to another, or even from one river to some other river in another part of the country. The faith of engineers, however, in the ancient errors with regard to the tides which we have mentioned, has been already somewhat shaken, and the practical information contained in the book before us will, we trust, explode them entirely, even if it should fail to establish any sound theory on the ruins of the old hypotheses.

In the 5th and 6th chapters Mr. Stevenson resumes the subject of the actual survey of the river, treating first of the low water survey, which embraces the sand banks, shoals, and other parts of the bed, which are dry at low water, and then of the high water margin, the method of proceeding to the best advantage being pointed out as to both these parts of the survey. We regret that our space will not admit of an extract sufficient in length to do justice to the author's views and explanations in this part of the work; we must, therefore, refer our readers for further information to the book itself.

The next chapter, on cross sections and borings, is interesting and useful, as exhibiting the most direct manner of proceeding to make sections across the river, at places where they are necessary to show the inequalities and structure of the bottom, and to point out the parts to be excavated in order to obtain sufficient depth of water in the channel. Mr. Stevenson justly observes that "much time may be lost in making the sections and borings, and erroneous data may be obtained if the operation be not gone about in a proper manner."

Chapter 8 relates to hydrometrical observations, principally on the velocity of currents at the surface, and the bed of their course. For the purpose of determining the mean velocity from the observed surface velocity, Mr. Stevenson gives the following formula, founded on a rule of De Buat:

$$\gamma = \frac{a + (\sqrt{a-1})}{2}$$

where a = the observed surface velocity, and γ = the mean velocity sought.

The concluding chapter, relating to the protraction of the lines in the survey, and of the soundings, completes the subject, and although this part is equally valuable, and in its mode of treatment equally practical with the rest of the book, it would convey little or no information to make isolated extracts from it. The whole, however, is well worthy the attention of every engineer and surveyor engaged in the prosecution of marine surveying, to all of whom it may be said, without derogation of their skill, that however practised or proficient they may be in this part of the profession, this book is calculated to add to their knowledge of the subject. The work contains numerous plans and sections of rivers, showing the mode of surveying and of representing the cross sections and borings, also examples of the manner of keeping the field books in the different stages of the survey.

BOOK MAKING.

SIR—I beg leave to trouble you with a few remarks respecting a recent publication, with the view of calling your attention to a highly reprehensible practice, which is now becoming common in this class of works. The practice I allude to is the copying and inserting, in several different publications, the same cuts and impressions. In a small work lately published, entitled "Anglican Church Architecture, &c." naturally supposing that the wood cuts and illustrations (with which the volume is rather copiously furnished) were examples not before published, but had been collected by the author to illustrate and support the opinions put forth in his work, I was induced to become a purchaser; but on looking over the book, I was much surprised to find that almost without exception the cuts, &c. were fac-similes of those published in a recent work entitled "The Glossary of Architecture," and as both proceed from the same publisher, I have no doubt the same blocks did duty a second time. It may be said that the work I now refer to is small in price, but the principle is equally bad, whatever may be the cost of the publication; and I hope that you will, by making instances of this sort of book-making public, prevent a practice so vicious in principle and so hurtful in its effects from becoming general. If persevered in, it cannot fail to destroy that confidence which should always subsist between the author and the purchaser of his work.

ON SPIRES.

We have already borrowed largely from the Penny Cyclopædia, on the subject of staircases, and now similarly avail ourselves of the article "Spire," which is certainly the most complete and most original we have ever yet met with. In fact, scarcely anything at all relative to spires is to be found in preceding publications,—not even in those which profess to be strictly architectural. They give us little more than an explanation of the term, and some not even that; at least, such is the case with Nicholson's Architectural Dictionary, where, unaccountable as it may seem, the word "Spire" is altogether omitted! Besides calling attention to a variety of interesting particulars that seem to have entirely escaped the observation of others, the writer of the article in the Penny Cyclopædia has suggested several new and expressive terms that, in our opinion, are well worthy of being generally adopted. We are aware that some persons object to any innovations of the kind, yet if they are found to be really useful, and to enrich the terminology of the art, there can be no impropriety in adopting them; neither is there any greater difficulty attending the introduction of them than arises from the attempt to revive terms which have become so entirely obsolete, that their original meanings can now only be vaguely guessed at, so that there is danger of the terms so rescued from oblivion being applied very differently from what they were in use.

"SPIRE (in German *Spitze*, or *Thurm-Spitze*; in French, *Flèche*, from its resemblance to the pointed tip of an arrow; but the Latin *spira* signifies a coil, or spiral line, and not an upright cone or pyramid). The term belongs to Gothic architecture, and is used to designate the tapering pyramidal mass erected on a tower by way of finish and ornament. That so little relative to spires is said in works on Gothic architecture is the more remarkable, because, in proportion to the number of examples, they exhibit more variety than almost any other separate feature in edifices in that style. Though the spire is a very striking feature in a building, it has nothing to recommend it on the score of direct utility. It is a mere external appendage to an edifice, since it does not, like the dome, contribute to any kind of effect whatever internally, a circumstance that seems to have been overlooked by Mr. A. W. Pugin, for else he would hardly have made it a reproach against the architect of St. Paul's, that the exterior dome of that fabric is merely for effect. Though the same objection might be made to the spire, we are far from urging it: mere utility is a low test of merit in architecture, and although this merit cannot be claimed for this feature in Gothic architecture, we hold the spire to be one of paramount value in it, inasmuch as that pyramidal figure concentrates all its principles and characteristics, rendering it most eminently the *Pointed* style. So considered, the spire may be said to be the key-stone of the whole idea of such style;—that which visibly completes it. It serves, moreover, to impart an air of graceful lightness to the whole of a building, and to correct—if we may so express it—what might else be excess of length as compared with the general height of a structure, by giving a corresponding degree of loftiness to one portion of it.

"The origin of the spire, like that of the pointed arch, is merely matter of conjecture. The probability is that it arose out of the peaked roof usually given to campaniles and towers of a preceding period, which form was afterwards gradually improved upon and refined, till it eventually grew up into the slender tapering spire. According to such supposition, we would refer to the tower of Than church in Normandy, as an example exhibiting the rudiments of the spire, it being no more than a steep peaked roof or low pyramid, whose height does not exceed three-fourths of its base. A peak of this kind differs also from the spire, both in being the same in plan as the tower on which it is placed, and in being immediately set upon it, whereas the spire is almost invariably an octagon or other polygon, and is surrounded at its base with a parapet. In Italy, where campaniles are usually detached square towers of very slender or lofty proportions, the spire is almost unknown, for such towers have seldom more than a mere pyramidal roof or peak, which, though it may be considered as the germ from which the Gothic spire was afterwards developed, is in itself of quite different character; yet, at the same time, that of each is best adapted to the respective style. There are some few instances of square spires; among them a very singular one at Egel in Germany, where two such spires are set immediately together upon the same tower. But however slender in their proportions such spires may otherwise be, they have a certain heavy massiveness of form. When therefore, greater loftiness and lightness were aimed at in this

feature, the adoption of a polygonal plan for it became almost matter of course, for although in a geometrical drawing the general outline and proportions of a spire are the same whether it be square or octangular in plan, the perspective or actual appearance is widely different; because in the latter case the diagonal breadth of the square tower below is cut off, and each side or plane of which the spire is composed becomes a much more pointed triangle. Besides which, the polygonal spire produces a degree of contrast and variety highly favourable to general effect in the pointed style."

* * * * *

"There are so many peculiarities in spires, that it is highly desirable to have descriptive terms for them. First, as regards its base, a spire may be said to be *Cluster-based*, when surrounded below with pinnacles connected with it, and from among which it seems to spring up; of which kind St. Mary's Oxford, is a celebrated example. The Hôtel-de-Ville, at Ypres, has a spire clustered with four exceedingly tall pinnacles or lesser spires. Where there are windows placed *against* a spire, rising *upright* like the dormers or lucarnes on a *foro*, the term *Lucarned* would express that character; we have therefore not scrupled to make use of it in the annexed table of spires, where it is applied, among others, to those of Lichfield cathedral, which have several tiers of such windows, and are described accordingly. *Crockelled* and *Banded* are terms requiring no explanation; but in regard to the first it may be remarked, that spires, otherwise quite plain, are sometimes ornamented with *crockets* along their edges; and with respect to *bands*, they are sometimes little more than string mouldings, but in other cases broad and enriched surfaces. Many of the spires in Normandy are ornamented with such a number of bands, that they form alternating courses with the plain spaces between them. *Finialled* is a term which does not apply to any of our English spires; but that of St. Stephen's, Vienna, and some other continental spires, have an exceedingly large and rich finial, which ornament gives them a particular boldness of expression. The *Tabernacle-spire* also is one of which there is no example in this country, but of which the one just mentioned, and those of Strassburg, Ulm (as designed), Thann in Alsace, and many others, are specimens, the tower and spire being carried up from the ground in a succession of diminishing stages, all profusely adorned with panneling, niches, canopies, pinnacles, and other tabernacle-work, in such a manner that it is barely possible to distinguish where the upright portion or tower terminates, and the spire itself begins, the latter seeming little more than the uppermost stage in continuation of the rest. Neither have we any instances of *Open-work* spires, or of such as, if not actually perforated, are yet entirely covered with tracery. That at Freyburg, and those at Burgos and Batalha, are all exceedingly rich specimens of the kind. The chapter-house of Burgos also has a series of very large pinnacles or small spires of tabernacle character. Cambrai and Esslingen on the Neckar afford other examples of open-work spires.

"There are various other circumstances which, though they do not affect the spire itself, produce greater or less difference in regard to the character of the structure of which it is a component feature. Very much, for instance, depends upon its situation in the general plan: at Salisbury, Norwich, and Chichester, the spire is raised upon a tower at the intersection of the cross, or in the centre of the plan; whereas in most continental cathedrals and large churches there are two spires on the towers of the west front, though in some instances (Strasburg, Antwerp) only one has been erected. Several, however, have a single tower and spire in the centre of the west front (Ulm, Freyburgh, Thann in Alsace), in which case the tower itself begins to diminish almost from the ground, and the whole becomes what we have described as of the *tabernacle* character. In most of our English churches (not cathedrals,) the spire is placed upon a tower at the west end, as at Grantham, Louth, Bloxham, &c. If we except Peterborough, where they are very diminutive, the only English cathedral which has two western spires is Lichfield, which is further remarkable as having a central tower and spire also. Besides the richness and variety thus produced, the larger central spire serves to balance the whole composition, whereas else the body of the structure is apt to look low in comparison with the west end. At St. Stephen's, Vienna, the tower and spire are singularly placed on the south side of the edifice, it having been intended to balance them by a corresponding tower on the north side. At Gelnhausen, on the contrary, there is a group of spires, as already noticed, at the east end."

Having extracted so largely from this Article, we must refer our readers to the Penny Cyclopædia itself for the remainder, transferring to our own pages the annexed Table:—

TABLE OF SPIRES, ENGLISH AND FOREIGN.

	Tower.	Spire.	Total Height.	Remarks.
Old St. Paul's . . .	260	274	534	Six diameters high.
Salisbury . . .	207	197	404	Date about 1350. Three enriched bands. Nearly five diameters.
Norwich . . .	140	163	303	Plain, rather more than five diameters high.
Lichfield . . .	114	138	252	Lucarned, 5 tiers of windows. Nearly 5 diameters high.
Do. two western . . .	89	103	192	Lucarned, 4 tiers; 4½ diameters high.
Chichester . . .	..	..	270	Pinnacled and lucarned below; banded with one broad rich band; else quite plain.
Oxford Cathedral . .	94	52	146	Date about 1220.
Oxford, St. Mary's . .	86	94	180	Spire itself quite plain, lucarned with a canopied window below, on four sides.
Louth . . .	148	140	288	Embased by very rich canopied niches and pinnacles.
Grantham (about) . .	140	..	250	Embased with lofty pinnacles and flying buttresses. Crocketted. 6 diameters.
Newark . . .	..	..	..	Lucarned, crocketted, large crocketted pinnacles at base. Base of spire less than tower.
Bloxham . . .	101	94	195	Short spire, spreading out at its base. Lucarned, with 4 tiers of windows.
St. Michael's, Coventry	136	164	300	A very beautiful example. Spire 5 diameters high. Date about 1350.
St. Mary's, Stamford .	..	..	..	This tower and spire a very fine example.
Welford, Gloucester .	..	..	..	Date about 1260. Base without parapet or pinnacles. Lucarned, 4 tiers. Spire 2½ diameters.
St. Chad's, Birmingham	88	62	150	An example of a spire on a low circular tower. Lucarned at its base with lofty gabled windows. Spire 3 diameters.
Cologne (as designed)	330	200	530	Two west towers, only N.W. spire yet erected. (<i>Comp. to Almanac, 1842.</i>)
Strasbourg . . .	364	110	474	Two west spires enriched with tracery, and crowned by large finials.
St. Stephens, Vienna .	285	180	465	Two west towers, only N.W. spire.
Ulm (as designed) . .	320	171	491	On south side of church. Example of a tabernacle tower and spire.
Freyburg . . .	221	159	380	Tabernacle example. Tower and spire in centre of west front.
Marburg . . .	184	88	272	Rich open-work spire. Tower and spire in centre of west front.
Nürnberg, St. Laurence	180	90	270	Two west towers and spires. Base of spire gabled. Spire 4½ diameters.
Nürnberg, St. Sebaldus	170	90	260	Do. do. do.
Thann in Alsace . . .	..	..	..	Do. do. do.
Antwerp . . .	..	..	366	A tabernacle example, with rich tracery-work on spire. Spire about one-fourth of entire height.
Chartres . . .	..	..	..	Two west towers, only N.W. spire.
Bayeux . . .	142	104	246	Two west spires, the N.W. one loftier and more enriched than the other.
Caen, St. Stephen's . .	155	107	262	Two west spires. The N.W. spire has 6 broad bands; the other plain. Diameter at base 27 feet.
Caen, St. Peter's . . .	134	110	244	Lucarned at base and banded.
Batalha . . .	113	57	170	Base of spire 24 feet. Spire has 9 bands, with small hexafoil, quatre-foil, and trefoil apertures between them. Crocketted.
Burgos Cathedral . . .	..	..	..	Very rich open-work spire. Diameter at base 19 feet.
Glasgow . . .	115	105	220	Two short or stump but very rich open-work spires, at west end. Date of spires 1442.
Treves on the Moselle .	111	128	239	Lucarned, banded, lower band richly moulded and quatre-foiled, and surmounted by fleurons. Diameter at base 27 feet.
St. Marie Hilf, Munich	220	60	280	A new church, finished 1831. Lassaulx, architect. Spire, a <i>broach</i> , splayed off at base. Diameter, above splay, 16 feet; height about 8 diameters.
				Church erected by Ohlmüller; completed 1839. Spire an open-work <i>helm</i> or <i>broach</i> .

ON WARMING AND VENTILATING THE REFORM CLUB.

Report on the Apparatus erected in the Reform Club House, for Warming and Ventilating its several Apartments. By ANDREW URE, M.D., F.R.S., Professor of Chemistry.

THERE are two general plans in use for at once diffusing heat, and renewing the air in extensive buildings, which plans differ essentially in their principles, modes of action, and effects. The oldest, and what may be called the *vulgar* method, consists in planting stoves in the passages or rooms, to give warmth in cold weather, and in constructing large and lofty chimney-stalks to draw air in hot weather out of the house, by suction, so to speak, whereby fresh air flows in to maintain, though imperfectly, an equilibrium of pressure. In apartments thus warmed and ventilated, the atmosphere is necessarily rarer than it is out of doors, while, in cold weather, the external air rushes in at every opening and crevice, of door, window, or chimney—the fruitful source of indisposition to the inmates.

The evils resulting from the stove-heating and air-rarefying system, were, a

few years ago, investigated by me, in a paper read before the Royal Society,* and afterwards published in several scientific and technological journals. It is there said, that the observations of Saussure, and other scientific travellers in mountainous regions, demonstrate how difficult and painful it is to make muscular or mental exertions in rarefied air. Even the slight rarefaction of the atmosphere, corresponding to a low state of the barometer at the level of the sea, is sufficient to occasion languor, lassitude, and uneasiness, in persons of delicate nerves; while the opposite condition of increased pressure, as indicated by a high state of the barometer, has a bracing effect upon both body and mind. Thus, we see how ventilation, by the powerful draught of a high chimney-stalk, as it operates by pumping out, exhausting, and attenuating the air, may prove detrimental to vivacity and health; and how ventilation, by forcing air in with a fan or a pump, is greatly to be preferred, not only for the reason above assigned, but because it prevents all regurgitation of foul air down the chimneys, an accident sure to happen in the

* I had been professionally employed by a Committee of the Officers of the Custom House, to examine the nature of the malaria which prevailed there, but I had no concern in erecting the stoves which caused it.

former method. Genial air thrown in by a fan, in the basement story of a building, also prevents the stagnation of vapours from damp and miasmata, which lurk about the foundations of buildings and in sewers, and which are sucked in by the rarefying plan. Many a lordly mansion is rendered hardly tenable from such a cause, during certain vicissitudes of wind and weather.

The condensing plan, as executed by the engineers, Messrs. Easton and Amos, at the Reform Club House, consists of a large fan, revolving rapidly in a cylindrical case, and is capable of throwing eleven thousand cubic feet of air per minute, into a spacious subterranean tunnel under the basement story. The fan is driven by an elegant steam engine, working on the expansion principle, of five horses' power. It is placed in a vault, under the flag pavement, in front of the building; and as it moves very smoothly, and burns merely cinders from the house fires, along with some anthracite, it occasions no nuisance of any kind. The steam of condensation of the engine supplies three cast iron chests with the requisite heat for warming the whole of the building. Each of these chests is a cube of three feet externally, and is distributed internally into seven parallel cast iron cases (somewhat like empty portfolios), each about three inches wide, which are separated by parallel alternate spaces, of the same width, for the passage of the air transversely, as it is impelled by the fan. This arrangement is most judicious, economizing fuel to the utmost degree; because the steam of condensation which, in a Watt's engine, would be absorbed and carried off by the air-pump, is here turned to good account, in warming the air of ventilation during the winter months. Two hundred weight of fuel suffices for working this steam engine during twelve hours. It pumps water for household purposes, raises the coals to the several apartments on the upper floors, and drives the fan ventilator. The air, in flowing rapidly through the series of cells placed alternately between the steam cases, cannot be scorched, as it is infallibly with air stoves; but it is heated only to the genial temperature of from 75° to 85° Fahr., and it thence enters a common chamber of brickwork in the basement story, from which it is let off into a series of distinct flues, governed by dialled valves or registers, whereby it is conducted in regulated quantities to the several apartments of the building. I am of opinion, that it would not be easy to devise a better plan for the purpose of warming and ventilating a large house; and I am only sorry to observe, that the plan projected by the engineers has been *injudicially* counteracted in two particulars.

The first of these is, that the external air, which supplies the fan, is made to traverse a great heap of coke before it can enter that apparatus, whereby it suffers such friction as materially to obstruct the ventilation of the house. The following experiments, which I made recently upon this point, will place the evil in a proper light. Having fitted up Dr. Wollaston's differential barometer, as an anemometer, with oil, of specific gravity 0.900 in one leg of its syphon, and water of 1.000 in the other, covered with the said oil in the two cisterns at top, I found that the stream of air produced by the fan, in a certain part of the flue, had a velocity only as the number 8, while the air was drawn through the coke, but that it had a velocity in the same place, as the number 11, whenever the air was freely admitted to the fan by opening a side door. Thus, three-elevenths, both of the ventilating and warming effects of the fan, are lost. I cannot divine any good reason for making the Members of the Reform Club breathe an atmosphere, certainly not improved, but most probably vitiated, by being passed in a moist state through a porous sulphureous carbon, whereby it will tend to generate the two deleterious gases, carbonic oxide and sulphuretted hydrogen, in a greater or less degree. It is vain to allege that these gases may not be discoverable by chemical analysis—can the gaseous matters which generate cholera, yellow-fever, or ague, be detected by chemical re-agents? No, truly; yet every one admits the reality of their specific virus. I should propose that the air be transmitted through a large sheet of wire-cloth before it reaches the fan, whereby it would be freed from the grosser particles of soot that pollute the atmosphere of London. The wire-cloth should be brushed every morning. The second particular, which counteracts in some measure the good effects of the fan in steam ventilation—is the huge stove placed in the top story of the building. This potent furnace, consuming, when in action, 3 cwt. of coals per day, tends to draw down foul air for its own supply from the chimneys of the adjoining rooms, and thus to impede the upward current created by the fan. I have measured by Dr. Wollaston's differential barometer the ventilating influence of the said furnace stove, and find it to be perfectly insignificant—

may, most absurdly so—when compared with the fan, as to the quantity of fuel which each requires per day. The rarefaction of air in the stove chamber, in reference to the external air, was indicated by a quarter of an inch difference of level in the legs of the oil and water syphon, and this when the door of the stove-room was shut, as it usually is; the tube of the differential barometer being inserted in a hole in the door. The fan indicates a ventilating force equal to two inches of the water syphon, which is twenty inches of the above oil and water syphon, and therefore eighty times greater than that of the stove furnace; so that, taking into view the smaller quantity of fuel which the fan requires, the advantage in ventilation in favour of the fan is the enormous ratio of 120 to 1, at the lowest estimate. The said stove in the attic seems to me to be not only futile, but dangerous. It is a huge rectangular cast iron chest, having a large hopper in front kept full of coals, and it is contracted above into a round pipe, which discharges the burnt air and smoke into a series of horizontal pipes of cast iron, about four inches diameter, which traverse the room under the ceiling, and terminate in a brick chimney. In consequence of this obstruction, the draught through the furnace is so feeble that no rush of air can be perceived in its ash pit, even when this is contracted to an area of six inches square: nay, when the ash pit was momentarily luted with bricks and clay, and the tube of the differential barometer was introduced a little way under the grate, the level of the oil and water syphon in that instrument was displaced by no more than one-tenth of an inch, which is only one-hundredth of an inch of water—a most impotent effect under a daily consumption of 3 cwt. of coals. In fact, this stove may be fitly styled an *incendiary coal devourer*, as it has already set fire to the house; and though now laid upon a new floor of iron rafters and stone flags, it still offers so much danger from its outlet iron pipes, should they become ignited from the combustion of charcoal deposited in them, that I think no premium of insurance adequate to cover the imminent risk of fire. The stove being, therefore, a superfluous and dangerous nuisance, should be turned out of doors as speedily as possible. Its total cost, with that of its fellow in the basement story, cannot be much less than the cost of the steam engine, with all its truly effectual warming and ventilating appurtenances.

I take leave to observe, that the system of heating and ventilating apparatus constructed by Messrs. Easton and Amos in the Reform Club House, offers one striking and peculiar advantage. It may be modified at little expense, so as to become the ready means of introducing, during the sultriest dog-days, refreshing currents of air at a temperature of 10, 20, 30, or even 40 degrees under that of the atmosphere. An apparatus of this nature attached to the Houses of Parliament and Courts of Law would prove an inestimable blessing to our legislators, lawyers, judges, and juries. Of such cool air a very gentle stream would suffice to make the most crowded apartments comfortable, without endangering the health of their inmates with gusts of wind through the doors, windows, and floors.

It is lamentable to reflect how little has been done for the well-being of the sentient and breathing functions of man in the public buildings of the metropolis, notwithstanding our boasted march of intellect and diffusion of useful knowledge. Almost all our churches are filled on Sundays with stove-roasted air; and even the House of Commons has its atmosphere exhausted by the suction of a huge chimney stalk, with a furnace equal, it is said, to that of a 40-horse steam boiler. To gentlemen plunged in air so attenuated, condensation of thought, and terseness of expression, can hardly be the order of the day.

Nearly seven years have elapsed since I endeavoured to point public attention to this important subject in the following terms:—"Our legislators, when bewailing, not long ago, the fate of their fellow-creatures doomed to breathe the polluted air of a factory, were little aware how superior the system of ventilation adopted in many cotton mills was to that employed for their own comfort in either House of Parliament. The engineers of Manchester do not, like those of the metropolis, trust for a sufficient supply of fresh air into any crowded hall, to currents physically created in the atmosphere by the difference of temperature excited by chimney draughts, because they know them to be ineffectual to remove, with requisite rapidity, the dense carbonic acid gas generated by many hundred powerful lungs."

* *Philosophy of Manufactures*, p. 380, published by Charles Knight. London, 1835.

At page 382 of the work just quoted there is an exact drawing and description of the factory ventilating fan.

On the 6th of June, 1836, I took occasion again, in a paper read before the Royal Society, upon the subject of the *malaria* which then prevailed in the Custom House, to investigate the principles of ventilation by the fan, and to demonstrate, by a numerous train of experiments, the great preference due to it, as to effect, economy, and comfort, over chimney-draught ventilation. Yet at this very time, the latter most objectionable plan was in progress of construction, upon a colossal scale, for the House of Commons. About the same period, however, the late ingenious Mr. Oldham, engineer of the Bank of England, mounted a mechanical ventilator, and steam chest heater, for supplying a copious current of warm air to the rooms of the engraving and printing departments of that establishment. Instead of a fan, Mr. Oldham employed a large pump to force the air through the alternate cells of his steam chest. He had introduced a similar system into the Bank of Ireland about ten years before, which is now in full action.

About two years ago, Messrs. Easton and Amos were employed to ventilate the letter carriers' and inland office departments of the General Post Office, of which the atmosphere was rendered not only uncomfortable, but insalubrious, by the numerous gas lights required there in the evenings. This task has been executed to the entire satisfaction of their employers, by means of fans driven by steam engine power. The said engineers made, about the same time, a set of machinery similar to that erected at the Bank of England, for warming and ventilating the Bank of Vienna. They are justly entitled to the credit of having been the first to execute, in all its bearings, the system of heating and ventilating buildings, having special respect to the health of their inmates, which I urged upon the public mind many years ago.

As fans of sufficient size, driven by steam power with sufficient velocity to warm in winter, and ventilate at all times, the most extensive buildings, may be erected upon the principles above described, without causing any nuisance from smoke, it is to be hoped that the Chapel of Henry VII. will not be desecrated by having a factory Vesuvius reared in its classical precincts, and that the noble pile of architecture of the new Houses of Parliament will not be disfigured with such a foul phenomenon.

* The following engravings, which we borrow from the *London Journal*, show the construction of the iron cases.

Fig. 1 is a transverse vertical section of the steam chest, for heating the air; fig. 2 is a plan of the same; and fig. 3 is a perspective view, showing the outside casing, also the pipe *a*, for admitting the steam, and the stop-cock *b*, for allowing the condensed water to escape.

ON IRON AS A MATERIAL FOR SHIP-BUILDING.

At the last general monthly meeting of the Liverpool Polytechnic Society, the president, John Grantham, Esq., C. E., read a paper *On Iron as a material for Ship-building*.

Mr. Grantham commenced by stating that it was not without some hesitation he ventured to occupy the time of the meeting with an inquiry into the advantages of using iron as a material for ship-building—an inquiry which was of deep and growing interest, and of great importance to the port of Liverpool. He had sought for practical information from others on the subject, but, having scarcely received any of a practical nature, he determined to take an independent course, and trust to his own observations rather than waste his efforts on a fruitless search. In this he had been materially assisted by the knowledge he possessed of the qualities of iron; and, as a proof of the sincerity of his views, he observed that he had come

to the determination, in conjunction with other gentlemen, of engaging seriously in the business of building iron vessels.

It was a mistake to suppose that vessels had only been recently constructed of iron. He was in a position to prove that the construction of iron vessels was not an invention of recent date—that the value of iron in this respect had long been known, and that it had been making a slow but a sure progress towards its present improved state. Iron vessels had been built for the English canals so far back as forty years since, and some of them, he had reason to believe, were still in existence. The first iron vessel that put to sea was built by the Horseley Iron Company, and was called the Aaron Manby, after the name of the projector. She was constructed in the year 1820, and had been at work ever since, without requiring any material repairs. The next iron steam vessel with which he was acquainted was built by the Horseley company under his father's superintendence. She was put together in Liverpool, in the year 1822, and proceeded to her destination, Lough Derg, on the river Shannon. She had been constantly at work ever since, and was at present in good condition. She was now the property of the Shannon company, who had six iron steam vessels at work, all in excellent condition. Several iron vessels had been built in England. The first built in Liverpool was by Messrs. Fawcett & Co., at their boiler yard in Oil Street. One of the vessels built by this company was called the Alburka, and went on Lander's unfortunate expedition to Africa. Several other iron vessels had since been built, of which some of those sailing from Liverpool to Glasgow were most conspicuous. Iron steam vessels had been employed in fighting our battles in the east, among which the *Nemesis* acted in the Chinese war. The *Ironside* steamer had been built in Liverpool, and was the first vessel of the kind, of any magnitude, that ever went to sea.

Mr. Grantham then proceeded to describe the ordinary method of constructing iron vessels, which he illustrated by diagrams and models. Iron vessels, he said, were constructed of plates fastened by angle iron ribs placed in different directions. He then described the construction of the keel, the bow, the floorings, the ribs, the platings, and the plan of double and single rivetting. He said that experience alone could decide the question as to the best disposition of the plates. He expressed himself in favour of the lap joint, and said it was groundless to suppose that the rivets could easily be driven out of their places, for, although the head might be removed, the remainder of the rivet was almost immovable. After showing that there existed great facility in applying stringers in iron vessels, he proceeded to make some remarks on the peculiarities possessed by iron vessels, and to institute a comparison between them and timber ones. In the construction of a vessel a builder should study strength, great stowage, safety, speed, durability, lightness of repairs, cheapness, and draft of water. He said he was in a condition to prove that iron vessels possessed all those qualifications in an eminent degree, and that they were superior in those several respects to timber vessels. In the first place they possessed great strength. It had been asserted that iron might answer very well as a material for the construction of small vessels and not very large ones. This, however, was not the case. The country was deprived of some of its finest oaks in order that timber vessels might be constructed, while there was no particular form into which iron could not be moulded by the smiths of England. In the latter case they had no sap to encounter, no knots, no cutting across the grain; and every inch of material was, moreover, of value. It was a well known fact that timber, after having been in use for some time, became brittle and could not be bent; but good iron did not become brittle. The facility for obtaining iron beams in one piece removed many difficulties.

The lecturer next instituted a comparison between the modes of fastening iron and timber vessels, and instanced the case of a copper-fastened timber ship, and the dreadful creaking of timber vessels at sea. He then alluded to the shock which had been some time since received by the *Nemesis*, and said that if a similar shock had been received by a timber ship the flooring of the latter might have been broken. The damage done to the *Nemesis*, however, had only amounted to about 30%. He said he could relate many other instances of the strength of iron vessels in comparison with timber ships, if time permitted. He next alluded to the qualification of stowage. He said the shell of a timber vessel was greater than that of an iron one, and that while a timber vessel could carry 200 tons, an iron one of similar size could carry 250. In the case of steamers, the comparison was much more in favour of iron as a material for ship building. The qualification of safety was in a great measure identical with strength. In addition to the extraordinary strength of an iron vessel, it would be almost impossible for a fire to take place in the hold if proper precautions were used, and the atmospheric air excluded. After showing the superiority of iron vessels over tim-

ber in point of speed, he referred to the qualification of durability, which, he said, involved a chemical question. Upon this subject he had been favoured by Mr. R. Mallett, of Dublin, who had been employed in making experiments for the British Association on the corrosion of cast and wrought iron, with a short paper on the corrosion or fouling of iron ships, which was of great interest, and would be published with the report of the lecture. He then referred to the qualification of durability, and said, that in removing the timber work of the ship John Garrow the dry rot was found. All the timber not exposed to the air had been affected by it, while that exposed to the air was perfectly free from corrosion. The lecturer here exhibited an iron bolt which had been taken out of the John Garrow. The part of it which had been in oak was very much corroded, while the remaining part of it which had been in iron was very little decayed. He was of opinion that oxidation took place no faster on the surface of thick plates than on thin ones, and he did not believe that the thickness of wood had any effect on its durability, so far as decay was concerned. The wear and tear of iron vessels were trifling, while the expense of their repairs was light. In a timber vessel, the expense of repairs would, in the course of ten years, equal the first cost. In the case of an iron vessel no repairs would, in all probability, be required within the first ten years. The expense of keeping the copper of a timber ship in repair would amount to a sum equal to that of making the whole of the repairs required by an iron vessel.

The first cost was the next point for consideration. He wished ship-owners to recollect that if they wanted good work they should give a proportionate price, and he hoped in future that they would obtain good work, and not be looking after a saving of expense. He had arrived at the following conclusions, in order to convey some idea on the subject:—that good serviceable iron sailing vessels, of 300 tons, would be equal to timber ships of larger tonnage; that iron vessels had many advantages over timber ones; that for very large vessels iron would be less expensive than timber; and that iron vessels for rivers might be built at a less expense. He laid less stress on the last qualification—that of light draught of water—than on others, but, at the same time, a light draught of water might be obtained in iron vessels. It would be asked, therefore, why not have iron vessels more generally built, if their superiority was so apparent? He would not evade this inquiry, neither would he forbear from alluding to the narrow policy of those who had opposed the system. He admitted that there were some real objections which had to be removed. Those objections had now, however, been set at rest. The difficulty about the compass was one, and it was natural that the derangement of the compass on board of iron vessels would have been a great obstacle; but this question had been entirely set at rest to all reasonable minds. Shipwrights and various other parties had also risen up against iron as a material for ship-building; everything was magnified, and it had been attempted to put it down once and for ever. It was broadly stated that iron vessels would never succeed; and when an iron vessel arrived in the port on one occasion, many went to look at her, and every possible fault was found with her. These objections were now becoming weaker. He thought some blame was attributable to the builders of iron vessels, and he called on builders not to place the principle of iron vessels in jeopardy by constructing vessels which their judgment might tell them would not be serviceable. Underwriters had not been the last to find objection, for shipowners had been told that the premiums would be very high on iron vessels, and that the subject had not been sufficiently tested. The shells which adhered to the bottoms of iron vessels had caused another objection to be raised. There would, however, be no difficulty in removing the shells when first they adhered to the bottoms, if a scraper were used, and this might be done by the sailors when they were at liberty during the voyage. After explaining the manner in which the scraper was to be used, he said that if the vessel were kept clean before she left the port, and the scraper was used at sea, the shells would be removed, and an iron vessel would be kept as clean as a timber one.

The lecturer here expressed a hope that he had satisfied many doubts, and awakened an interest in the breasts of some who never reflected on the subject before. He instanced the fact that chain cables, steam navigation, and many other inventions, had been met with opposition in the first instance, although in general use at present, and he prophesied that such would be the case with reference to iron as a material for ship-building. He said he had a description before him of the "*Great Britain*" steam ship, but that the lateness of the hour prevented him from entering into details. He then referred to the facility which existed for altering iron ships, and said that while the iron could be used again, the fact was otherwise in many cases with respect to timber. He thought there could not be a better period than the present for considering a question of the present kind as a means for alleviating

the general distress. If taken up as a national question it would be attended with beneficial results. No one would deny that it was of importance that our ships should be constructed in our own ports, by men of our own population, and with materials of our own soil, which materials were obtainable in the deep recesses of the earth. The iron could be got at the usual market price; there would be an increased demand for labour; and few foreign timber ships could compete with English vessels, as all countries yielded the palm to England in the use of iron. There appeared to him to be only one obstacle to be removed—he alluded to national prejudice. The English public were unwilling to give up their "old wooden walls." It seemed as if they thought their glory would depart if they were to surrender on this point; but it should be remembered that the noblest specimens of naval architecture possessed the seeds of decay, and that the royal heart of oak would remain in the land, if iron were brought into general use. There was one other result which the lecturer noticed, namely, that a 400-ton ship would not produce £200 when condemned and broken up, while an iron vessel, under similar circumstances, at 4s. per cwt., would produce 2l. per registered ton, or four times as much as a timber ship.

He then concluded by saying that the present was the first time the subject had been fairly before the public, and by hoping that he had advanced it somewhat in the estimation of the meeting, and that in their progress, rise, and end, wooden ships might yield to iron. The reading of the paper, which occupied upwards of two hours, was received throughout with demonstrations of applause and satisfaction.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

Jan. 11.—The PRESIDENT in the Chair.

"Description of a portion of the Works of the Ulster Canal." By Thomas Casebourne, M. Inst. C. E.

The Ulster Canal, which is described in this communication, was designed for the purpose of facilitating the intercourse between the west and the north of Ireland. It commences at the southern extremity of Lough Erne, in the county of Fermanagh, whence it extends for a length of 46 miles, and enters the river Blackwater, near the village of Charlemont, in the county of Armagh, from which there is an outlet through Lough Neagh to the ports of Newry and Belfast. The total cost of this work will amount to about 210,000l., or 4,565l. per mile. Allusion is made to a proposed junction canal between the rivers Boyle and Shannon, which may be considered as an extension of the Ulster Canal westward, effecting a junction between all the navigations of Ireland. By its means the produce of the town of Boyle, and the agricultural district around it, would be conveyed directly by steam to Belfast and Newry. At the time of this communication, the Ulster Canal was rapidly advancing towards completion; it was navigable up to Clones, a distance of 40 miles from its commencement, and would be opened to Lough Erne during the summer of 1841. A description is given of the most difficult and expensive portion of the canal, which is situated at about six miles along the line from Charlemont. The length of this part is about three-fourths of a mile, and it comprises seven locks. The expense of construction, exclusive of the value of land, was 17,053l. 4s. 9d.; in order to diminish the expense as much as possible, the canal was contracted in width in two points, where the local impediments were considerable. The transverse dimensions of the canal are, 19 ft. 6 in. at the bottom, 36 ft. at the surface of the water, and 42 ft. at the top bank—giving a slope of 3 to 2 at the sides of the channel. The depth of water is 5 ft. 6 in. in all the reaches, except the summit level, which is capable of containing 7 feet of water. The course of this portion of the line lay along the bottom of a steep ravine in a limestone rock, parallel with the channel of a mill-race adjacent to the river Blackwater. The mill-race was, therefore, diverted into the river between the first and fifth locks of the canal. Between the third and fifth locks the bed of the canal was formed by benching in the rock on one side, and embanking on the other with the materials so obtained. Beyond this it was cut for a distance of nearly 350 yards through the limestone; in one place to a depth of 41 feet. The sides and bed were there lined with puddle, and protected by a facing of rubble wall. Thence, to the seventh lock, the channel was again formed by benching and embanking through a clay soil, where much caution was necessarily exercised in preventing slips at the foot of the embankment, which was subject to inundations from the Blackwater. The masonry was all constructed of limestone from an adjacent quarry. Two appendices are subjoined to this paper. The first of these gives in detail the items of expenditure for the portion of the canal described; the second contains a particular description of the locks and lock-gates, the bridges, and the earth-work. The locks are 73 ft. long, 12 ft. wide, and vary in rise from 6 to 11 feet. They are all constructed in ashlar masonry.—The paper is accom-

panied by three drawings, descriptive of the general plan and the details of these works, which were originally designed by Mr. Telford, and are now under the direction of Mr. Cubitt. They have been executed almost entirely under the superintendence of the author.

"An account of the Permanent Way of the Birmingham and Gloucester Railway." By G. B. W. Jackson, Grad. Inst. C. E.

The object of this railway is to afford a direct communication between the western and the midland counties of England. The communication describes the course of the line until it reaches Cheltenham, where it joins that which was formerly called the Great Western and Cheltenham Railway, which terminates at Gloucester. Its length is 54 miles. The prevailing inclination is 1 in 300; but on the "Lickey" incline, near Bromsgrove, the rise is 1 in 37 for a distance of $2\frac{1}{2}$ miles, in ascending which the trains are worked by American locomotives, in addition to the usual train engines. The northern portion of the railway appears to lie on the new red sandstone; then passes to the oolitic formation, on which it terminates. In the former, the principal cuttings are through marl, some of which is exceedingly indurated, and troublesome to work. The principal strata of the latter system are blue and yellow clays. Near Cheltenham, the shifting sand frequently necessitated the use of sheet-piling in passing through it. The waters of Droitwich and Cheltenham were found to possess a saline quality, which rendered them unfit for the use of the engines. That from the surface sand near Cheltenham, however, is exceedingly good.

The building materials employed on this line were—the sandstones of the Lickey and Forest of Dean, the lias of Norton and Wadborough, and the oolites of Cheltenham and Bredon, together with brick, for which earth was readily produced throughout. The cuttings and embankments, with the details of the permanent way, are severally described. The surface width is 30 feet. In the formation of embankments and cuttings, the usual methods appear to have been adopted. In the former, the ratios of the slopes vary between 3 and $2\frac{1}{2}$ to 1; in the latter, between 2 and $1\frac{1}{2}$ to 1. In cuttings, there is a system of drainage beneath the ballast, consisting of longitudinal drains on either side of the line, connected by cross spits, all of which are filled up with broken stones. The rails are supported by chairs and intermediate saddles, which rest on longitudinal balks; and these are bolted to transverse ties. On embankments whose height exceeds five feet, the cross spits, longitudinal balks, and saddles, are all dispensed with. The length of the bearings, the weight, dimensions, &c., of the iron and wood work, with the manner of putting together the whole, are then noticed. The timber employed was, American pine, and English beech, or larch. The various prices are enumerated of the materials and labour for the permanent way, of which the average cost per mile amounted to 5,430*l.* The present condition of the line is stated to be good, and its general working to have been perfectly satisfactory, since its opening in June, 1840.

Subjoined is a description of an artificial ballast obtained by burning clay, which was employed when the country did not afford natural ballast. Its expense slightly exceeds that of the ordinary ballast; blue clay burnt in kilns was found to answer the purpose best, but it does not appear to form a successful substitute for gravel. The results of experiment show it to form a very imperfect drain. The author states that he has always observed the quality of this ballast to suffer in proportion with the quantity of lime contained in it composition.—The paper is accompanied by four drawings, illustrating the construction of the permanent way.

"Description of a Water-pressure Engine at Illsang in Bavaria." By William Lewis Baker, Grad. Inst. C. E.

The machine described in this paper is the most perfect among nine engines constructed by M. de Reichenbach, for the saltworks at Illsang, in Bavaria. These important works are situated in the most southern part of the kingdom; they are supplied from a mine in the valley of Rerhtesgacten, and the salt springs at Reichenhalle. The salt was procured from the former in two states,—that of rock salt, which was extracted by blasting, and that of brine. The rock salt was conveyed to Reichenhall, and there underwent the purifying process. But both these methods were attended with disadvantages from the scarcity of fuel; the old method was therefore abolished, and a line of pipes of seven inches diameter was substituted; it was laid between the two places, and extends about 60 miles in length. A series of water-pressure engines, each working a forcing pump, and being themselves worked by a head of water, were placed in convenient situations upon the line. The mine is now worked by forming cavities in the beds of salt, and filling them with water, which soon becomes strongly saturated brine; it is then pumped up, and forced through the pipes to Reichenhalle, where a portion of it is retained, and the rest is sent on to Franenstein, which is at the extremity of the line. At these places, the process of evaporation is carried on, and the salt is manufactured in the usual manner.—The paper is illustrated by a drawing of the engine, showing the details of construction alluded to in the communication.

INSTITUTE OF BRITISH ARCHITECTS.

Feb. 28.—H. E. KENDAL, Esq. in the Chair.

THE principal business of the evening was to decide on the merits of the drawings and essays submitted to the Institute for their annual prizes.

The Soane Medallion was awarded to Mr. John W. Papworth, associate, for a restoration of Crosby Place, Bishopsgate, as it may be supposed to have existed in the 16th century. To the medallion, a premium of ten guineas has, on this occasion, been annexed, by the liberality of Miss Hackett, the lady to whose antiquarian taste and zeal the public are mainly indebted for the preservation of the Hall, and other remains of this beautiful monument of the domestic architecture of the middle ages.

The medal of the Institute was awarded to an essay*—*"On the effects which should result to Architectural Taste, from the general use of Iron in the Construction of Buildings."* In this essay, (which was read to the meeting,) the writer argued, that a new style of architecture ought to arise from the introduction of a new material, to the extent to which the practical application of cast iron may be, and indeed has already been, carried; and that it is a blot upon the inventive faculties of the age, that art has done little or nothing with a material which has proved of such vast importance in the hands of science. It was further argued, that nothing, probably, but prejudice stands in the way of the development of as much beauty, in a style adapted to the extensive employment of cast iron, as in styles adapted to marble, or any other material. To strike out new combinations and characteristics, the writer did not profess; but that they might be struck out in strict accordance with the principles which govern beauty and taste, he inferred, from the practice of the ancients, who have left us works of art in the most opposite extremes of proportion, and yet equally admitted to be beautiful; the proportions and principles of beauty being governed by the materials in which they are executed, in support of which proposition he cited the candelabra, tripods, chairs, and other works of antiquity in marble and bronze, contrasting the characters of these objects, destined for the same purposes, and exhibiting the same general designs; and that this principle may be carried into architecture, we have also the authority of the ancients, who not only conceived, but systematized a style of architecture of extreme lightness and delicacy, although we do not know that it was ever carried into execution, except with the brush—alluding to the architectural frame-work of the ancient fresco paintings. Instead of working upon such lessons as these, the modern architect has, hitherto, used one of his most important powers in construction only in disguise—misled by pre-conceived ideas on taste. In considering the characteristics of Gothic architecture, which formed a second division of this essay, this practice was shown to be still more absurd, since cast iron lends itself with the utmost facility to this style, especially in its earlier periods, when it appears to have been a principle to reduce the supports, not only apparently, but really, to a minimum, of which the Lady Chapel, of Salisbury, offers proof. In this portion of his subject, therefore, the writer sought to reconcile the use of cast iron with existing principles of taste, and pointed out the peculiar modes which the architects of the middle ages adopted in tracery when executed in metal, as evidenced by the screens of Edward IV. and Henry VII's tombs, contrasting them with modern cast iron window frames modelled upon precedents in stone. The conclusion drawn was, that whenever prejudice shall give way, and iron be recognized as a legitimate resource in art, new architectonic combinations will be produced; and that in Gothic architecture especially, we shall have at our command effects, of which our predecessors could only dream, although they made bold efforts to realize them.

The Honorary Secretary reported, that an answer to the address of the Institute to Prince Albert had been received through the hands of the President, Earl De Grey, and that H.R.H. had been graciously pleased to become the Patron of the Institute.

ARCHITECTURAL SOCIETY.

A CLOSING conversazione of the Architectural Society was held at their apartments, in Lincoln's-inn-fields, on Tuesday evening, March 1st, on the occasion of the juncture of that society with the Institute of British Artists. The rooms were crowded with the leading architects, engineers, and artists of London. The chair was taken by the late president of the Architectural Society, William Tite, Esq. F.R.S., &c.

The chairman prefaced his address by a rapid glance at the state of architecture in England up to the close of the late war, when the opening of the continent furnished the artists with models, and gave a stimulus to their exertions of the most useful nature. The spread of information and of education led to the demand for means of co-operation and combination which the Royal Academy did not furnish, and in consequence, about twelve years ago, the two societies, in connection with architecture, arose. The Architectural Society was first in point of time, but the Institute obtained a charter, and thereby the means of conferring the honorary distinctions of fellow and associate. The plan of the two societies was at first very different, but they had gradually assimilated: and in consequence of a general feeling that a junction was desirable, Mr. Tite was (with the sanction of his Royal Highness the Duke of Sussex, the patron of the Architectural Society) authorised to communicate with Earl de Grey, the president of the Institute on the subject. His Excellency forwarded the suggestion by every means in his power, and after the necessary meetings of the two bodies, the junction was effected early in the last month, the members of the two societies being then

* The essay is anonymous, and no claimant has come forward to receive the medal.

united, and the library, casts, and prints will be immediately removed to the rooms of the Institute in Grosvenor-street. Mr. Tite concluded this part of his address by a well-deserved compliment to his Royal Highness the Duke of Sussex for his kind and effective patronage of the society.

The official part of the president's address having been concluded, he proceeded, in completion of a series of four papers upon the antiquities of Egypt, three of which he had read at previous conversaciones, to give an account of the labours of Colonel Vyse and Mr. Perring in opening and examining all the pyramids of Middle Egypt, thirty-nine in number, from Abou Roach, just north of Cairo, to Illahon, about fifty miles south of that city. All the pyramids of Gizeh Sakkara, and the other interesting sites were explained and elucidated in a most able manner, with the assistance of an exhibition of a large series of the prints and drawings themselves; and every point of interest to the engineer, the architect, and the archæologist was traced out in its turn. The original dimensions of the great pyramid near Gizeh are so vast as to be almost incredible. This pyramid was stated to have been originally 764 square feet at the base, and 480 feet of perpendicular height, covering 13 acres, 1 rood, 22 perches of ground; it consumed 89,028,000 cubic feet of stone, and Mr. Tite stated that it could not now be built for less than 30 millions sterling. The joints of the large casing blocks of granite were so fine as to be scarcely perceptible, not thicker than paper, and the mortar was so adhesive that the stones in some cases broke through their substance rather than give way at the jointing. All the pyramids, with one exception, are due north and south, and are all entered on the north. They are intended as mere mausolia, and generally contained only one sarcophagus each, and rarely more than two. The hieroglyphical discoveries brought to light by these labours, as explained by Mr. Birch, of the British Museum, distinctly showed that the construction of the three great pyramids must be ascribed to a period 2,000 years before Christ, and that they were built by the three kings, Cheops, Cephrones, and Mycerenus, to whom their erection was attributed by Herodotus and the Greeks. The sarcophagus which contained the body of the latter king in the third pyramid, which was richly ornamented, and composed of one block of beautiful basalt, weighing three tons, was removed from the pyramid, and safely placed on board a ship at Alexandria for the British Museum, but she was unfortunately lost near Carthage, on her way to England, and scarcely a fragment of the ship was seen afterwards, and not a soul was saved to tell the calamity. We have before had occasion to notice the learned and skilful papers of Mr. Tite, and this, like all the preceding ones, was a model of taste and judgment in its arrangement, and skill in its delivery.

After the lecture Mr. Grellier, the late secretary, addressed the meeting. He stated that this evening being the last time of his appearing before them in his official capacity of secretary to the late Architectural Society, he trusted that he might be favoured with their kind attention, while he discharged the pleasing task he had been deputed to perform from the body of gentlemen forming the late Architectural Society—to acknowledge and express to their President, Mr. Tite, the high sense of gratitude entertained towards him, for the kind, able, and efficient manner in which he had discharged, for a period of four years, the duties required of him as President of the late Architectural Society, and as chairman of its several meetings. And as many of the gentlemen present had witnessed his valuable services, and the urbanity he had evinced when presiding at the visitors' meetings, the gentlemen constituting the late Architectural Society had selected the present occasion as being the most appropriate and fitting opportunity of testifying their warmest thanks to Mr. Tite, for his constant and unwearied attention to the duties of his office, which, whether on public or private occasions, he has so zealously and faithfully discharged.

Mr. Grellier then read the following vote of thanks, that has been drawn up:—

ARCHITECTURAL SOCIETY, LONDON,
Instituted A.D. 1831.

His Royal Highness the DUKE OF SUSSEX, K.G., &c., Patron.

The Architectural Society of London, having been recently incorporated with the Royal Institute of British Architects, a meeting of the members of the Society was held at the apartments, No. 35, Lincoln's Inn Fields, on the 21st. February, 1842, for the purpose of expressing the high sense entertained by them of the services of William Tite, Esq., F.R.S., &c., their late President, when the following resolution was passed:—

"That the members of the late Architectural Society, on behalf of that Society, for themselves individually, and particularly on behalf of the students' class—do express to William Tite, Esq. their acknowledgments and thanks for his valuable and efficient services as President of the Society, and as chairman at their several meetings, during a period of four years.

"Also their opinion of the benefits rendered to the profession generally, by his constant exertions to promote the knowledge of Architecture as a fine art, and of those branches of science, which are essential to its practical application."

Signed, by order of the Meeting,

35, Lincoln's Inn Fields,
21st February, 1842.

WILLIAM GRELLIER.
Hon. Sec. to the late Architectural Society.

The secretary, turning to Mr. Tite, then said, "In the name of the Architectural Society, I have great pleasure in presenting you with this scroll, stating, as you have heard read, the reason why it was presented, and I can assure you that this form has not been selected without due consideration, believing it to be the most agreeable and acceptable to you. In conclusion, I have only to express a hope that in after years, when you may look upon the inscription herein recorded, that while you call to mind the time that you

have spent and the labours you have bestowed on behalf of the late Architectural Society, you may also remember that the gentlemen on whom you conferred those favours were neither unmindful of or ungrateful for them."

Mr. Tite acknowledged the compliment in a very feeling manner, and the business of the evening closed.

There were exhibited in the rooms some beautiful drawings and paintings by Messrs. Nixon, B. Moore, and other artists; also a very large drawing of the stained glass now being executed for the north transept of Westminster Abbey, by Messrs. Ward and Nixon. On the table of the second room was a model of the great building now being erected at Liverpool by the corporation, combining under one roof the great St. George's Hall, the assize courts, a large music hall, and various rooms and apartments for corporate purposes. This building is in a rich style of Corinthian architecture; it will be 500 feet long by about 90 feet in width. The architect is Mr. Elmes, jun.

Thus terminated the Architectural Society.

"THE SLIP" ON THE CROYDON RAILWAY.

SIR—I observe that your Journal contains reports of Mr. Vignoles' lectures at the London University College; and as the learned gentleman in some of these lectures indulges rather freely in observations upon the works of his brother engineers, I presume that he will neither be offended nor surprised to find that opinions different from his own are entertained by some, at least, of the numerous class of readers, who, by means of their publication in your Journal, are made acquainted with these lectures of his. To cavil upon minute points of professional practice, would be unworthy any man who considers the circumstances under which a lecturer on engineering comes before the public. I will, therefore, pass over many expressions and many accounts of expedients, some prospective and others retrospective, being already executed, which appear no doubt puerile enough to men who have themselves dealt with the elements, and studied engineering in the capacious school of nature, and come at once to the insinuations of the professor of and concerning "the slip" at New Cross on the Croydon Railway.

I find that the learned gentleman and his class, assuming the peripatetic style, have made expeditions in a body to the site of several works of engineering in the environs of London; and that one of these visits was paid to the scene of this celebrated slip, and on that occasion certain remarks were indulged in which I think in no way added to the dignity nor to the accuracy of the lecture. I now quote from your report of the lecture. "The professor then pointed out what he considered to have been the occasion of all the mischief. Nearly all along the slip, the earth had given way at the side of a top drain, parallel with the railway, and in some places it was so apparent, that the declivity looked as if made purposely; this had invariably occurred where there were cross drains from the neighbouring ground (which is considerably elevated), leading into the main drain along the top of the cutting, and which, not being puddled or made water-tight, had allowed the water gradually, and during many months, to insinuate itself into the veins in the clay, and had at length forced the mass out as it appeared."

Now, what is here meant? I am at a loss to understand, from the confused way in which the opinion is expressed, whether Mr. Vignoles asserted that the longitudinal drain along the verge of the slope was not puddled, or that this precaution was omitted in the transverse drains leading into it. If the former of these suppositions expresses what the learned lecturer meant, I beg to assure him, from the evidence of my own eyes, that he is decidedly in error, because every inch of this drain was well and completely puddled; but if he meant that the transverse drains also ought to have been puddled, I would merely observe that he is imposing an unnecessary and entirely useless expense upon the company. Let it be noticed, however, that I would not for a moment think of combating this or any other opinion of the learned gentleman, did it not involve, in some sort, the professional reputation of the engineer who executed this work, because if it be apparent that puddling ought here to have been resorted to, the engineer is of course to blame for omitting it.

Now to test this opinion, let us observe what difference of effect would the puddling of these drains have occasioned—simply that of preventing the water from penetrating through the bottoms of the drains. But would it have prevented water from penetrating the mass of the hill? Would it have cut off the supply of water from the porous strata where they crop out on the higher lands above? Clearly not. It is obvious that the surface of vegetable mould which covers the hill must be at least as permeable to water as the mass of clay on which the mould rests; yet the whole surface of the

hill is to be left unpuddled, and the whole attention of the engineer is to be directed to the object of making the base of the drains water-tight, notwithstanding these drains are all cut into the solid clay.

Mr. Editor, is not this pure nonsense? And what right has a lecturer, advancing such childish notions himself, to convey to his pupils an impression alike unworthy and unjust towards the engineer who executed this work. When the cutting was originally made, everything was done that was necessary; and as for the puddling of these drains, they might have been puddled for miles in length on each side of the railway, without contributing one single atom of benefit towards the prevention of the slips. Further on, the professor disapproves of what is being done by way of precaution, and recommends that "apertures should be driven in horizontally, and brushwood drains introduced, or a kind of hurdle or *fascines*, which would act as a drain, and be extremely efficacious. I do sincerely hope and trust that the Croydon Railway Company will never act upon this advice, because if these apertures are driven any distance into the hill, they will tap a much larger body of water than that which finds its way at present to the face of the slopes, and as soon as the drains become at all choked up, down comes a slip much more extensive than any that has yet happened; while on the other hand, if the apertures be not driven more than a few feet into the slope they will not catch the water which occasions the mischief, and thus for all the good they will do, might just as well have been driven so many feet into one of the mountains in the moon.

I am, Sir,

Your very obedient servant,

JUSTUS.

REMARKS ON DR. FULTON'S LECTURE.

SIR—Having perused Dr. Fulton's lecture on the "State and Study of Civil Architecture," as inserted in your March number, and considering some of the observations made by him to be incorrect, I venture to offer a few remarks on the same, hoping that if you have any superfluous room, you will favour them with a place in your next number.

And, first, with regard to the origin of pointed architecture, the lecturer asserts that it (together with the Saracenic,) was derived from the Roman, bringing forward as evidence the fact, that at Spalatro are found slender columns supporting circular arches with distorted human faces, introduced as ornaments; but at the same time he admits that the pointed arch is not found there. Now I would observe that the pointed arch is the elementary ingredient of the pointed style, and that without its presence a building cannot be regarded as of that style, so that to detect its origin is, in fact, to detect the origin of the style to which it belongs: I shall, therefore, endeavour briefly to show that Rome was not the originator of it. It is a well-known fact that the pointed arch made its appearance in the different countries of Europe at very nearly one and the same time, viz. just after the termination of the first Crusade; and this fact manifestly points to some one locality from whence all the nations of Europe among whom it sprung up must have derived the idea of it. Moreover, this must have happened at the same time, for if it had not, or if they had borrowed the one from the other, there would necessarily have been specimens in *our*, or at all events in *some*, of these countries, before the others had time to borrow it.

But if the Europeans all derived the idea of the pointed arch at one particular time, and from one particular place, it follows that *that* place must have been one of general rendezvous; and since the time in which it appeared was just after they had returned from the first Crusade, it is in a high degree probable that they obtained this idea from the East, or else from some of the countries through which they passed on their way thither. Now there are specimens found in the East of the pointed arch of a date anterior to the first Crusade, so that this circumstance appears to give a degree of assurance to the notion that the Europeans derived it from the Saracens; but admitting that they did not, still there is no evidence in favour of their having obtained it from the Romans, for I am not aware that the first Crusaders passed through Italy at all. Moreover, if they had, seeing that there was no actual specimen of the pointed arch to be found in those parts, they must have seen something in Roman architecture which *indirectly* conveyed to them the idea of it; and in this case it is extremely difficult to conceive that they should all happen to hit on the same train of reasoning, and thus, each for themselves, light upon the pointed arch.

In the second place, Dr. Fulton states that the Greeks did not leave even their Doric columns without bases, but that the steps on which they rested

formed an ample basement. I grant, indeed, that these steps did form an ample basement to the edifice, considered as a whole, serving both to beautify and strengthen it, but certainly not as a base to each individual column. His reasoning, too, is fallacious, for he says, "What would the finest statue that ever was made appear to be, with its feet sunk in the ground or cut off?" According to this, then, we must admit that the columns represented statues, and the stylobate their feet; and if so, what is the result? Why simply this; that the Ionic columns in the temple of Minerva Polias (for example), which not only individually have bases, but are collectively superimposed upon a stylobate, represent statues having a double set of feet, one over the other, which, to my mind, would be quite as devoid of beauty as statues with no feet at all.

The third and last point to which I shall take occasion to advert is the lecturer's objections against "gable-topped windows and doors," by which I suppose windows and doors crowned with pediments. His words are, "Of all the strange devices of which I have given a list, this is the most strange." And yet I cannot find out that he has assigned any reason why they are strange, unless indeed it is because he is "unable to discover the use of these window tops;" but if people ask the use of many things in architecture, we shall only have to answer, "Its use is to adorn the building;" and so here, the use of these gable tops is to adorn windows and doors, and to show that they do so in many cases, I need only refer to the lower range of windows in the Strand front of Somerset House, and to the one-pair windows of the Reform Club. Besides, if these gable tops be absurd in Palladian architecture, shall we not be obliged to condemn quite as much the beautiful pedimented canopies over the windows and doors of many of our pointed structures, as, for example, York cathedral; and who will say that they do not form an important element of beauty in those edifices?

With the remainder of Dr. Fulton's remarks I cordially assent; and hoping that I have not trespassed too long on your attention or that of your readers,

I beg to subscribe myself, Sir,

Yours respectfully,

G. W. R.

MORE ON FRESCO PAINTING.

WHILE the subject of fresco painting is in every one's mouth, and we have papers on the subject at the Institute, and lectures at the Royal Institution, it may be worth while to consider the best method for commencing operations.

At a late visit to Hampton Court, on entering the staircase to the gallery of the chapel, I was struck with the excellent opportunity there presented for an essay in this new style of art, by which additional interest might be given to a part of the building now but little visited, at a moderate expense, and with great advantage to our artists. The staircase is of oak, of the time of Queen Anne; the plan is a square of about 25 ft., and wainscotted about 8 ft. above the upper landing, leaving on their sides perhaps a dozen feet more of bare plaster up to the ceiling, and lighted by windows on the fourth. On these spaces, which are well calculated for this kind of decoration, the artists likely to be engaged with the new Houses of Parliament might be employed to try their hands. The situation is not one of such vast importance as to render the probable slight imperfections of a first attempt very alarming; and by beginning in this moderate way, the danger would be avoided of a failure in a more conspicuous situation, which might give an excuse to the timorous to call in the aid of the Germans, and for the enemies of innovation to abandon the thing altogether; and we may certainly hope that the earliest efforts of our artists, inexperienced as they are, would be superior to plain whitewash. Neither would they be induced to make their essays in situations where the paintings could not be permanent, and by that means, as far as everything but mere practice was concerned, throw away their time and materials to no purpose.

This locality is only mentioned as a specimen, of which hundreds might be found elsewhere, and many in the same building; all of which, besides perfecting the painters, would tend to make the style more generally known, and thus interest the public in it from its very commencement.

In the progress of this high style of art, much will depend on the architects; for if they oppose it, or do not recommend its introduction in their buildings, it can never be generally adopted.

J. L.

ON INCREASING THE EVAPORATIVE EFFECT OF BOILERS.

Sir—In my communication inserted in the last *Journal*, I assure you I had no desire unnecessarily to occupy your useful columns, by “taking a range of several months,” in replying to the very severe remarks of the reviewer of my “projects.” I trust, however, to your candour, in affording me an opportunity of setting myself and my “projects” right with your readers, not as to the personal matter, but to the scientific and practical details of the subject. Having disposed of the comments on my suggestions for increasing the evaporative boilers, by means of longitudinal conductor pins, I now come to that of the “smoke preventive plan.”

The reviewer observes—“Our philosopher says that combustion” (of the gaseous matter from the coals) “does not take place (in the furnace), inasmuch as he has doors to his ash pit, which he shuts immediately that the furnace has received a fresh charge, and which he keeps shut until the gas is all expelled.” To this I have only to say, it is entirely a gratuitous assumption. I am guilty of no such absurdity. That I recommend doors to ash-pits, as others have done before me, is true; not, however, for the sake of excluding the air, or producing an “hermetically sealed boiler furnace,” but of regulating its admission, as far as is practicable, to the ash pit and bars, the doors being furnished with suitable slides or registers; thus, in some measure apportioning the quantity supplied to the demand, and where, in ordinary furnaces, no attempt at any regulating means is made. The reviewer then goes into a lengthened refutation of this manifest absurdity, which happens to be exclusively the work of his own fertile invention; and which I need not further notice.

He then observes—“All smoke-burning projects operate upon the principle of admitting an excess of air into the furnace and flue, and this principle is attended with two insuperable objections. First, the refrigeratory effect of the great excess of air which it is necessary to admit to a mixture of the gases, to accomplish the indispensable condition of combustion—proximity of the atoms to be combined; and second, the impracticability of apportioning the admission of air to the ever-changing quantity of smoke evolved.” Now here are two important and clearly enunciated terms; and my reply is, that it is expressly to correct these two evils that my plan applies, viz. the preventing this refrigeratory effect, by rendering an “excess” of air unnecessary; and second, the aiding the operations of nature, by removing that very obstruction to the process of diffusing this “excess” of air. And here I would just hint at a chemical error under which the reviewer labours; inasmuch as the “great excess of air” he speaks of, as being necessary to a “mixture of the combustible and incombustible gases, in accomplishing the indispensable condition of combustion—the proximity of the atoms to be combined,” is a very serious impediment, rather than a necessary aid, to that very condition. For this well-established chemical fact, (as my opinions are too “insane” to merit attention,) I beg to direct the reviewer to Davy’s “Researches on Flame.” And may I not here be allowed to remark, in a spirit of good humour, that if I be that “ponderous gentleman” whose “attendants should insinify with a few grains of common sense,” other persons may possibly consider my would-be guide as that imponderous and light-headed reviewer, whom it would be well to ballast with a few grains of chemical knowledge, to qualify him for steering his own bark, before he undertakes to correct the reckonings of others. But, badinage apart, this very “excess of air,” which is here laid down as “necessary,” is as great an enemy to proper diffusion and perfect combustion, as a deficiency would be; but on this, it is unnecessary here to dwell. To correct this impracticability of apportioning the admission of air to the “ever-changing quantity of smoke evolved from an ordinary furnace,” I separate the air into two supplies, thus rendering them more manageable, and, what is more important, less liable to interfere with and mar each other’s objects; a system, also, which has this practical value—the causing them to be, to a great extent, mutual correctors of each other’s defects. The one supply is sent to the ash pit and bars, for the combustion of the solid carbonaceous portion of the fuel; the other to the gaseous matter evolved from it.

But I ask, why shall this want of a more correct means of regulating the supply of air to the demand, be so peculiarly chargeable on my mode of admission; while the ordinary plan of furnaces is so lamentably and wholly deficient on this head—nay, even absolutely prohibitive of any attempt at regulation? My mode, to a great extent, practically corrects the evil (as I am now showing in my papers on this subject in the *Mechanic’s Magazine*), while, by the ordinary method, the supply of air is most restricted by the body of fresh fuel on the bars, at the very time when an increased quantity

is most required, by reason of the increased quantity of gas evolved. The absence, then, of the means for “adjusting the quantity of influent air to the variable condition of the fire,” bears with infinitely greater force against the old plan, so pertinaciously adhered to, and which rejects any effort towards adjustment. Again; although this variable supply of air required has reference to the gaseous matter evolved above the fuel, rather than to the solid matter on the bars, yet these sticklers for a regulating valve would absolutely compel the supply of air which is intended for such gaseous matter to pass through such bars and body of incandescent fuel, where it necessarily loses much of its oxygen, if not the whole; thus virtually sending the smallest quantity of oxygen to the gases when they were most redundant. Let those, then, who cavil for a regulating valve, first apply the argument to their own old favourite system before they object to mine, which practically and to a great extent meets the difficulty.

The reviewer next observes—“But the parturient mountain has again brought forth a mouse. This learned philosopher, after vapouring about atoms and gases, presents us with—what? a veritable antique smoke-burning furnace.” If this be true, then we must be prepared to call the Argand burner a veritable smoke-burning lamp. This sneer at “vapouring about atoms and gases” I must say is, at least, inappropriate from that pen which had just before truly and scientifically urged the “indispensable condition of combustion—the proximity of the atoms to be combined”—the very point on which the whole atomic theory, as regards the union of gases, rests its value. Again; I am told “the sole peculiarity” of my plan is that “the air enters by a greater number of holes than usual.” Will the reviewer inform your readers whether this peculiarity be not the very one which characterizes the Argand burner? Again; “whether, of two smoke-burning projects, the least objectionable is that which admits the air at one hole, or that which admits the air at many holes, it would here be irrelevant to inquire.” Now, Sir, that is the real point worth inquiring into; and this blinking the main question at issue will not go down with your scientific readers, unless he can first persuade them that there is no difference between the brilliant smokeless burners in our shops in Regent-street, and those flaring smoking flames which the butchers’ stalls exhibit; the sole difference being that which is here said to be irrelevant—namely, the difference between the one large hole and the many small holes. For, chemically, the effect is the same, whether the air be admitted in jets to the gas, or the gas in jets to the air—my mode of admission being, in the words of Professor Brande, “an experiment upon the large and practical scale which I have often made on a small and theoretical scale, in illustration of the inaccuracy of the common terms ‘combustible,’ and ‘supporter of combustion,’ as ordinarily applied.”

“We are informed,” says the reviewer, “that Mr. Bourne has a patent for the same thing of the date 1838.” I beg to say the reviewer is misinformed. Mr. Bourne’s patent is for the generation of gas from retorts placed in a furnace over the incandescent fuel on the bars, and, when the gases are expelled from these retorts, drawing the solid coke from them on to the bars below, to keep up the body of incandescent matter. It must, therefore, be to this invention that Dr. Lardner and Mr. Farey’s reports apply. But it matters not; for if this identical “same thing” be so good under Mr. Bourne’s name, it cannot be so very insane under mine. On the merits of the actual invention of Mr. Bourne, I forbear to speak; of the actual plan of a furnace which he afterwards adopted in the steamers on the Thames, after having rejected his own, I have already said enough in my treatise, where I have given it in proof of one of the erroneous modes of effecting the combustion of the gaseous products of coal: neither will I say anything of Mr. Bourne’s anonymous essay, now before me, out of respect to Mr. Bourne himself.

But perhaps the gravamen of the charges against my presumption in questioning the practice of our “operative engineers,” may be discovered by the concluding observation, that “engineers and boiler-makers know their business much too well to lack information from a pack of effervescent chemists and druggists”—meaning the first chemical authorities of the day, Professor Brande, Dr. Ure, Dr. Kane, Professor Daniell, &c. I beg leave to assure the reviewer that many of the first engineers and boiler-makers have, in a manner worthy this inquiring age, expressed themselves in a very different manner, urging me to pursue the inquiry, and follow up those experiments on the large scale which have so opened their eyes to the defective system and empirical rules, on which they have hitherto relied.

I am, Sir,

Yours, &c.

C. W. WILLIAMS.

Liverpool, March 15.

MR. WILLIAMS' BOILER PROJECTS.

SIR—The appearance in your Journal for February of a paper purporting to be an analysis of Mr. Williams' boiler projects, seems to call for some explanation on the part of those whose investigations on the subject may have led them to other conclusions than those arrived at by the ingenious author of that essay. Just advert to the critical acumen displayed in deriving the authorship of a communication to the London Mechanics' Magazine, to which the author's name happens to be prefixed, or the peculiar character of the internal evidence which led the learned analyst to the unexpected conclusion that Mr. W. was the writer of the paper which Mr. W. read before the Polytechnic Society, I may perhaps be permitted to make one or two observations before proceeding to reply to the details of the critique.

That the first of a series of papers devoted to the development of a department of physical science, hitherto almost untrodden or giving only the most discordant results, and uniting the deepest interest with the greatest abstruseness, should be selected as a peg whereto to append a string of most ludicrous corollaries, evidences the existence of a spirit of such jocose and sprightly philosophy, that one is a little at a loss in what strain to reply. Perhaps the best answer would be, affectionately to admonish the writer to read a little farther, and acquire a little more thorough acquaintance with the subject than the perusal of a prefatory chapter can convey. At the same time, I am well aware that to criticise a subject it is not necessary to be intimately acquainted with it—nay, the very negation of acquaintance will sometimes be found marvellously to facilitate the operation, and the more skilful the reviewer, the less need will there be for the preliminary drudgery of first studying the subject, so that a very able writer indeed will have no difficulty in writing a very good article on a subject he knows nothing about at all.

To enter minutely into the possible modes of action of the conduction pins, whether as facilitating combustion by assisting the interchange of electricities essential to chemical action, or as aiding the generation of steam, on the same principle that internal asperities in an evaporating vessel facilitate the process of vaporization, would be to write a treatise instead of (which is our present object) to reply to an objection. Let us, then, for the present, confine our attention to the conducting power alone of the pins whose action has been attended by such striking effects.

We know, by the experiments of M. Delarive, that the conducting power of some substances of a fibrous texture, such as wood, varies exceedingly according as conduction takes place in a direction transverse or parallel to the fibres. We are thus prepared to expect similar results in the case of those metallic bodies in which the fibrous arrangement is strongly marked. It is true we do not possess accounts of experiments made to determine the relative amount of lateral and longitudinal conducting power in such bodies; but there are phenomena connected with the transmission of heat through solid bodies, which would lead to the conclusion that it follows different laws in different though similar substances, and that general theories, founded on the supposition of uniformity of action among the consecutive elements of different bodies are not to be depended upon.

For instance, it has been found that in some cases, increasing the dimensions of the conducting substance in the direction of the conduction, produces very slight retardation in the passage of the heat, a fact sufficient to destroy all confidence in reasonings founded upon the ordinary hypothesis of a rapidity of transmission proportional to the difference of temperature of the contiguous elementary laminae of which we may conceive the body to be composed. We are thus prepared—I do not say to adopt the conclusion—but to listen to the arguments which may lead to the conclusion, that the power of transmitting heat depends on something more than mere inequality of temperature in the consecutive elements. In the case of an ordinary steam boiler, we do not know the temperature of either the interior or exterior surface of the plates; all we know is, that the one cannot be hotter than the flame, nor the other colder than the water contained, but between these limits we know nothing; and we are still further removed from a knowledge of the laws which regulate the communication of the heat, and the approximative equalisation of the temperature.

With these observations let us now consider the action of the pins, on the supposition (certainly not a correct one) that the stratum of air in contact with the boiler surface and the whole length of the pins, is of uniform temperature. We in this case naturally expect that the lower extremities of the fessing considerable economy of fuel, should make the removal of these

pins will attain a higher temperature than the exterior surface of the boiler, and we may conceive that that section of the pins which lies in the plane of the outer surface of the boiler, may differ more or less in temperature from that of the outer surface itself; but the rapidity of the transmission of heat may proceed according to very different laws, and the greater difference of temperature between the extremities of the pins, combined with the greater facility afforded by increase of surface, for the reception and giving out of heat, may occasion such an increased intensity of transmissive action as to cause a greatly increased flow of heat into the boiler, and that the evaporative power is increased in a much higher ratio than the consideration of the actual increase of heating surface would lead us to expect, appears from experiments that have been made on a large scale. So great, in fact, has been this disproportion, that we are compelled to investigate the action of the conduction pins, on another and more likely supposition, which, however, is so much in accordance with the laws of nature, that it ought rather to be adduced as an explanation than adopted as an hypothesis. Instead, therefore, of considering the boiler surface and the whole length of the pins to be enveloped in an atmosphere of uniform temperature—which is almost an extravagant supposition—we shall take into account the cooling agency of the boiler surface on the stratum of air in contact with it. Now at the high temperature of common furnaces, from 1000° to 2000° F., a given depression of temperature will occasion a diminution of volume of only from $\frac{1}{4}$ to $\frac{1}{2}$ of what would take place at ordinary temperatures, and a correspondingly diminished ascensional force in the lower contiguous stratum. But this ascending stratum will be cooled to a certain extent by crossing the other, and the resulting temperature of the succeeding film that comes in contact with the boiler will be lower than that of the stratum removed a little farther from the cooling surface. Thus a refrigerating action is carried on, and the longer the operation continues, the greater will be the uniformity of the temperature attained throughout the mass. But when we consider the rapidity of the current through the flues, ascertained by Dr. Ure to be not less than 36 ft. per second, we are led to the conclusion, that the process of refrigeration cannot have penetrated to a great depth before the heat-giving atmosphere has quitted the flues entirely, and that the lower extremities of the pins must be enveloped in an atmosphere of higher temperature than that from which the bottom of the boiler derives its heat; while in the anterior part of the boiler, this will be still more marked, almost the whole projecting length of the pins being exposed to a rapid current at a very high temperature, while the partially refrigerated gases will glide along the surface of the plates.

When we consider the temperature of the air in the smoke-box of a locomotive in full action, known to equal that of red hot iron, after submitting to the operation of a refrigerating mechanism so much more complete than that to which the products of an ordinary furnace are subjected, we can no longer view with incredulity, or even with surprise, the results of the experimental investigation that demonstrates the efficacy of the conduction pins.

We have hitherto confined our attention to the action of the pins in a horizontal or nearly horizontal surface; in the case of an inclined or vertical surface, the preceding train of argument is still more applicable. In this case the descending current of air, instead of tending to quit the surface to which it has given out its heat, will glide down the sides still preserving its contact, and giving out a diminished quantity of heat as it descends, while the outer extremities of the pins will be exposed to the action, at a high temperature, of a rapid current that would otherwise have been hurried along to the chimney, without giving out any heat to the boiler at all.

With regard to what has been denominated the second part of Mr. Williams' boiler projects, perhaps I might presume to tender similar advice to that which I gave before entering on the discussion of the conduction pins—not so much that the critic should peruse Mr. Williams' treatise on combustion, but that he should study the instructive and beautiful commentary on that work which the operation of the argand furnace presents, a commentary which possesses the advantage of being proof against misinterpretation, being an infallible mean of convincing those who are less accustomed to be guided by the deductions of their understanding than the impressions of their senses. As the gist of the argument of the reviewer of the "Projects" hinges on the definition of smoke given in a pamphlet entitled "Thoughts on Steam Locomotion," I may be permitted to transcribe a few sentences: "The great waste resulting from smoke, the product of imperfect combustion, which must be estimated not merely in the proportion of the unconsumed carbon, but also in regard to the heat which becomes latent in its formation, and is dissipated in the atmosphere, and the many inconveniences consequent on its formation—are such as to render it expedient that all schemes pro-

defects their starting point. Smoke may therefore be regarded as a mixture of combustible and incombustible gases, in such proportions as to prevent the combustion of the mixture with practical economy."

Smoke is here defined to be the product of imperfect combustion; but what are we to understand by the term "imperfect combustion;" there is no such thing in nature. Who ever heard of imperfectly formed carbonic acid, or of steam without a saturating equivalent of oxygen. In fact, the term "imperfect combustion" refers to a period in the history of science when the doctrine of chemical equivalents and the atomic constitution of bodies was still undeveloped, and though justified by common usage, yet language so unprecise is unsuited to philosophical definition, where precision is the great requisite.

The product of imperfect combustion must, therefore, be understood to mean, the products of perfect combustion, mixed up with what is not the product of combustion at all, or, in other words, a mixture of combustible and incombustible gases; but how this should ever come to be regarded as a definition of smoke—may, as being *par excellence*, "the very definition" by which must be tested the merits of all smoke-burning and smoke-preventing schemes whatever, is likely to remain a mystery till it please the author of "Thoughts on Steam Locomotion," to elucidate the subject in a second edition.

That a mixture of carbonic acid gas and olefiant gas, or of coal gas with nitrogen should produce smoke, even though "when taken they be well shaken," is a discovery, which I apprehend may look for its establishment to a period in the prospective history of science, nearly as remote as that to which we are referred in the retrospective, by the term imperfect combustion. And such it seems are the opinions on the constitution of smoke, to which it is alleged Mr. Williams was indebted for the views he has developed in his treatise on the combustion of coal. Let us now attend to the process of its formation, as explained in that treatise. We shall find it to be carbon precipitated from the state of gaseous combination or solution in which it had been held by hydrogen or other gases, forming, it may be, cyanogen or carbonic oxide, but principally the ordinary hydrocarbons. The decomposition of either of the former, or the partial combustion of the latter, may occasion smoke.

We shall, for the present, confine our attention to the hydrocarbons; and in the first place, smoke may be produced, if to the gas at a high temperature be presented a certain quantity of oxygen, but not sufficient to saturate both the elements composing the hydrocarbon. In this case the hydrogen, in virtue of its superior affinity, will combine with its equivalent of oxygen while the carbon will be precipitated, and when cooled below the temperature of ignition, will assume the form of smoke. Secondly, the reduction of the temperature below that which is required for chemical action, after combustion has commenced, is the other principal cause of the formation of smoke. In this case the decomposition of the hydrocarbon will go on, if there be any uncombined oxygen present, steam will be formed, while the carbon being cooled down below the temperature required for combustion, will speedily assume the form of smoke.

The cooling effect of a body of cold air suddenly admitted into a furnace, must be familiar to all who have studied the phenomena of combustion; smoke is produced immediately in consequence of the condensation and deposition of the aerial carbon previously held in solution by the hydrogen.

Let us now consider the arguments by which it is intended to be proved that Mr. Williams' furnace is in reality a smoke-burning and not a smoke-preventing. The substance of the argument is this; in Mr. Williams' furnace carbonic acid is first of all formed, and comes over mingled with the carburetted hydrogen produced by the destructive distillation of the coal. Here, then, is the product of imperfect combustion, a true mixture of combustible and incombustible gases, but this is smoke according to the very definition. When, therefore, we effect the combustion of the hydrocarbon in this impure state (or rather in this disreputable company), it seems that we do not burn gas but smoke. In short, the unlucky hydrocarbon is disfranchised at least, if not decomposed, by its unfortunate proximity to the product of combustion, with which it is more or less contaminated, becomes no longer entitled to the privilege of a combustible gas, but must prolong or terminate its existence as it may, under the ignominious character of smoke. A moment's attention to the actual constitution of smoke as explained above, is sufficient to show the absolute fallacy of the above conclusion. And when we consider that neither of the circumstances which concur in the formation of smoke have place in the argand furnace, viz. either deficiency of oxygen or an injurious reduction of temperature, we shall have no hesitation in according to Mr. Williams the merit of having produced a smoke-preventing furnace.

To enter further into an elucidation of the principles on which is founded the peculiarly happy and successful practice of Mr. Williams, would at this time of day be quite superfluous; the public are already in possession of full information upon the subject, and anything that could be stated here would be only a repetition of what has been better said elsewhere.

Sir, I am,

Your's, &c.

A. S.

"MR. CHARLES WYE WILLIAMS, AND HIS BOILER PROJECTS."

MR. EDITOR—The perusal of the article under this head in your last number, has induced me to trouble you with a few remarks upon the subject of combustion.

It has frequently been a matter of surprise to me, that so much has been written upon this important subject, with so little practical result. It is true we continually hear of experiments, by which some new smoke-consuming theory has been established beyond all question; but unfortunately, no sooner is this new light brought to the test of every-day experience in the stoke-hole, but it is found that, for want of the required degree of combination of either the oxygen, hydrogen, nitrogen, or carbon, that bi-carburetted hydrogen is generated, and from the absence of sufficient radiation of heat from the brick-work of the furnace, this dense olefiant gas is not decomposed, ergo is not consumed, and consequently it escapes up the chimney, to publish to the world the failure of the experiment. It is vain to attempt any explanation of the cause which has produced this effect, to the astonished stoker; all you get from him is a look expressive of unutterable things.

I can speak feelingly upon this subject, having some little time since had an excellent opportunity of testing the practical value of some of the most plausible propositions for economising fuel. About three years since, I was engaged by a Patent Salt Company to give designs for, and to superintend the construction of several of their furnaces, with a view to greater economy in the fuel department, the vital importance of which will be better understood, when I inform you that their annual consumption of coals averages 25,000 tons. It will not be necessary to go into a detailed account of the effects of my alterations of the furnaces in question, but simply to confine the following remarks to the general result of the various experiments. I was naturally anxious to avail myself of the assistance of every modern panacea, which had a sufficient degree of plausibility attached to it; and consequently jets of steam discharged upon the burning fuel; cold air admitted in various quantities, in different directions, through apertures of all sorts and figures; single fire doors, double fire doors, and no fire doors at all; register doors to the ash pit; bridges of diverse heights and arrangement; throats of all capacities; dampers in various positions, &c. (but I did not *spike* my boilers,) were severally and fairly tried under my own superintendence, for months; and the result of all these experiments was my settled conviction, that however well adapted these modes of combining some gases and decomposing others may be to the lecture-room or laboratory, that in every-day practice they are to a great extent useless, and that the chief desideratum has been lost sight of. This I take to be a regular and constant supply of fuel, thinly scattered over the surface of the fire; without the necessity of the frequent opening of the fire door.

Several attempts have been made to effect this desirable object, but none that I know of are as efficient as I think they may be made. I am at present too much engaged in another department to devote my time to this subject, but I think it would repay some of your readers to do so.

I am, Sir,

Yours obediently,

E. LEADER WILLIAMS.

St. John's, Worcester,
Feb. 9, 1842.

[The observations we purpose to offer in answer to the preceding communications we shall reserve for our next number. A portion of the letter of Mr. E. Leader Williams, as being irrelevant, we have omitted. We have also been obliged to omit a communication from Mr. Smith of Manchester, in support of Mr. Williams' views, but as the points urged by Mr. Smith are still more fully developed in the communication of A.S., Mr. Williams' cause can suffer nothing from this omission. As journalists we may sometimes be compelled to be severe, but we trust to be always impartial.—EDITOR.]

ON THE GORGON ENGINE.

SIR—I had expected to find in your February number some answer to the observations of "Vulcan" inserted in the preceding one; but, as none has appeared, I am induced to trouble you with a few remarks, in reference to the misrepresentations and fallacies contained in the letter alluded to.

The writer professes to found his criticisms upon statements contained, as he pretends, in a certain "pamphlet published by Messrs. Seaward and Co." Had this pamphlet been really published and publicly circulated, it would only have been necessary to refer your readers to it, in order to enable them, if they exercised common candour and common sense, to detect at once the errors (to use the mildest form of expression,) which "Vulcan" has thought proper to propagate; but unfortunately this pamphlet was printed only for private circulation, and I do not think a copy of it can be found at the British Museum or in any of the public collections, except that of the Institute of Civil Engineers.* "Vulcan" appears to have taken advantage of this circumstance to circulate and to attribute to the authors of the pamphlet statements which he must know, if he has read the work at all, it does not contain; and it is principally on this account that some exposé of his misrepresentations becomes the more necessary. I will endeavour to supply this, taking his different statements *seriatim* for the purpose.

He first attempts to show that no merit is due to Messrs. Seaward for the introduction of the engine of the description erected in the Gorgon; and in order to give colour to the detraction, it is pretended that the manufacturers have laid claim to the *direct application of the power as a new arrangement* of their own. This is, indeed, not expressly stated, but it is obviously meant to be inferred, or why enumerate engines "identical with the Gorgon so far as the direct application of the power goes?" On referring, however, to the pamphlet itself, we find the following passages—"These engines are constructed on the principle of *what is called* the direct action;" and again, "It should be observed, that many engines have been constructed, previous to the Gorgon engines, upon the principle of the direct action, but the arrangements of all those engines have been widely different." These expressly repudiate the claim to the introduction of the "direct action," *per se*, as an invention of the manufacturers; but it is well known that the arrangements of the minutiae of an invention often contribute as much towards its success as the principle on which it is founded; Messrs. Seaward, therefore, may be very well content to confine their claim to the merit of having, by new arrangements, rendered a principle efficient and applicable, which was never before so complete on a large scale.

For, what are the facts? Marine engines have undoubtedly been constructed with direct action, prior to the date of the Gorgon's, but with what success? The "Tourist" engines (with the arrangements of the *fixed* cylinders, "very like" Mr. Penn's *oscillating* ones,) never worked well, were removed from the vessel upwards of seven years ago, and common beam engines substituted; while those of the "United Kingdom," notwithstanding their "considerable improvements," and the assurance the writer feels of their "advantage over the Gorgon's," were, according to the best information I can obtain, in actual work only about four years, and are now taken out, the "splendid ship" itself being converted into a coal dépôt. At the time of the erection of the Gorgon engine there were no direct action engines of any importance in use: all the makers were constructing them upon the beam principle: but since that event what has been the result? I am informed that Messrs. Seaward alone have fitted eleven large vessels with these labelled engines, amounting together to about 3000 horses power, with the most perfect success; and many other firms, among whom may be mentioned Maudslays and Field, Boulton and Watt,† Miller and Ravenhill, Robert Napier, and Fairbairn & Co., are at the present time constructing engines with direct action. All, therefore, that "Vulcan's" instances prove, is, that Messrs. Seaward are the first who have succeeded in doing what Messrs. Gutzmer, Napier, and all who went before them, were unable to accomplish, namely, to make the direct action principle successful in practice, and to show that it is capable of realizing the advantages which have indeed heretofore been sought from it, but sought in vain.

Before noticing the remarks upon the *intrinsic* merits of the Gorgon engine, I will take the liberty of quoting the passage from Mr. Seaward's

pamphlet, in which the advantages are enumerated that this form has, as it is considered, over the beam engine. It runs as follows:—

"The advantages of the present system are very considerable, and consist of:—

"1st. *A great saving of space.*—A pair of Gorgon engines do not occupy much more than one-half the space required for a pair of beam engines of the usual construction.

"2nd. *A great saving of weight.*—The weight of a pair of Gorgon engines is 25 per cent. less than that of a pair of beam engines.

"3rd. *Greater exemption from accident.*—The simplicity of the arrangements, and the reduced number of moving parts, necessarily lessen the chance of accident, as also the wear and tear.

"4th. *Greater security for the engine-men who work the engine.*—There being no side levers or beams in movement, the men can move round the engines in every part with perfect safety; but they cannot do so with beam engines, without much danger.

"5th. *The tremor and vibration usually experienced in steam vessels are almost entirely prevented.*—The chief cause of the tremor and vibration observable in steam vessels, is the pumping action of the beams or side levers, which causes a great strain and effort throughout the whole vessel; but there is nothing of this in the Gorgon engines.

"6th. *A more efficient and economical application of the motive power,*—resulting from the absence of a large mass of moving matter, and of many joints and bearings, the latter of which especially, is in ordinary engines the cause of much loss of power."

I will leave your readers to compare this with "Vulcan's" paragraph, beginning "In a pamphlet," &c., and they will see how the writer has adhered to the text in his pretended quotations. It will be desirable to correct such of his statements as may have a tendency to mislead those who have not an opportunity of inquiring for themselves.

First, then, "Vulcan" denies that the Gorgon engines take up less space than the common ones, and has given your engraver the trouble of copying a "sketch" of the framing of some hypothetical and imaginary beam engine of his own, under the drawing of the Gorgon, for the purpose of substantiating his charge. I cannot deny to "Vulcan" the right of "sketching" beam engines in any manner and with any proportions or "architecture" he may think fit; but I will beg such of your readers as may take an interest in such matters to refer for comparison, *not* to "Vulcan's" "sketch," but to authenticated drawings of beam engines in actual existence, or to the engines themselves.

The following table exhibits a comparison of the length occupied by three of the engines upon the direct principle, with three others upon the old construction, the saving in *length* being in that part of the ship which is most valuable for stowage of cargo.

Name of Vessel.	Description of Engine.	Makers of Engines.	Horse Power.	Length of Engine room.
Gorgon	direct	Seaward	320	62
Driver	"	"	280	52
Hydra	beam	Boulton & Watt	220	62
Medea	"	Maudslays & Field	220	60
Vivid	"	Seaward	220	58
Devastation	direct	Maudslays & Field	400	54

The saving in *width* is so self-evident as scarcely to need remark, from the entire absence of all machinery outside the cylinder. It is this saving which enables vessels fitted with direct action engines to stow such large quantities of fuel on each side of the engine room.

Then as to the saving in *weight*, we have "Vulcan's" dictum that 0.93 tons per horse power is an "ample allowance for beam engines of the size of the Gorgon." This is very easy to assert, but not quite so easy to prove; I would ask him to particularize some engines which are of this weight, giving the makers' names, *the diameter of the cylinders*, &c., by which we may see that the comparison is fair, and that the horse power is calculated by the same rule as the Gorgon's. It is strongly to be suspected that "Vulcan" must make use of a higher estimate of the mean pressure upon the piston than the Thames engineers, as the Scotch frequently do in calculating the power of their engines; and if this be so, it is easy to perceive that he may call a certain engine 350 horse power, which in our nomenclature would be only 300.

* Nearly the whole of the pamphlet was published in the *Journal* for Nov. 1840, p. 375, Vol. III, and for Feb. 1841, p. 59, Vol. IV.—EDITOR.

† See engraving of the Virago engines in the February No. of the *Journal*

and his 0.93 ton per horse power would then amount pretty nearly to what is known to be the actual weight of beam engines afloat, namely, about 1 ton.

As a proof that this weight is not over-rated, I cannot do better than again tabulate some known engines of the best makers, giving their weights as compared with the Gorgon.

Name of Vessel.	Makers of Engines.	Horse Power.	Total Weight.	Tons per Horse Power.
			Tons.	
Gorgon	Seaward	320	280	0.88
Hecla	Scott & Sinclair	280	340	1.22
Stromboli	R. Napier & Co.	280	340	1.22
Monarch	Boulton & Watt	220	270	1.24
Medea	Maudslay	220	240	1.1

These weights include water in the boilers, spare gear, and coal boxes complete.

A word perhaps may be added upon another of Vulcan's "astounding facts," which he parades with much pomp and circumstance, namely, the incorrectness of the weight given by Messrs. Seaward to the Admiralty.* The estimated weight of the Gorgon engine (for the engine itself is all we have at present to do with, no alteration being proposed in the other portions of the whole weight,) was 121 tons: the actual weight, when manufactured, was found to be, adopting "Vulcan's" own statement, 123 tons, 3 cwt. That is, the actual weight was 2 tons, 3 cwt. greater than the estimate; an estimate, be it remembered, formed entirely by calculation, before a single part of the engine was put in hand, and while no other engine of the kind was in existence from which to obtain data. And this is the flagrant error, or something worse, with which Messrs. Seaward are charged, from which "your readers are desired to form their own conclusions," &c., and which "calls so loudly for explanation!"

The following facts, with which I have been furnished by a friend on whom I can rely, are I think, pretty conclusive as to the saving both of weight and space.

The Gorgon steam frigate of 1050 tons was built in 1837, and was originally intended to receive beam engines of 220 horse power, the bulk heads being placed 62 feet apart, the ordinary distance allowed for engines of that size. The estimated weight of these engines was given as 270 tons, including the coal boxes and the water in the boilers; and space was proposed to be allotted for 300 tons of coal.

This same vessel is now, without any alteration of her engine-room, fitted with engines upon the direct action principle, of 320 horse power, weighing less than 300 tons, and has provision for 420 tons of coal in store. Why the change was made, I do not know; but I believe the beam engines originally intended for the Gorgon are now in the Hydra, a smaller vessel but an excellent sailer.

Again, I may instance two vessels in the navy, now afloat. The Stromboli, with beam engines of 280 horse power, has an engine-room of 58 feet in length, and carries only seven days' supply of fuel in the engine-room, drawing, with her stores on board, 14 feet of water. The Driver, a sister vessel, built from the same lines, has direct engines, also of 280 horse power, in an engine-room of only 52 feet long, in which she carries 14 days' fuel, and the same quantity of stores, at the same draught of water.

The second division of your correspondent's critique is upon the friction of the engine. Your readers will observe, however, that there is no mention of any material advantage from lessened friction, in the quotation I have introduced from the Gorgon pamphlet, and I can add that no such pretension is made throughout the whole of the work; the object for which this subject is introduced there, being only to defend the engine from the charges brought against it by those who asserted that the loss by friction was materially increased by the use of the shortened connecting rod. "Vulcan" might, therefore, have spared himself pen and ink on this head, and had he contented himself with merely insisting that no very material gain arose from

this cause, his remarks might have passed unnoticed; but he has not been satisfied with simply chasing away the phantom he himself had conjured up; he has gone further, and, presuming I suppose upon his newly-acquired valour, he has levelled a heavy charge against the Gorgon engine, viz. that "the enormous friction caused by the short connecting rod is so great as to equal $\frac{1}{2}$ of the power of the engine passing through them." This renders a few words to him necessary.

He has thought proper to pay us, the readers of your valuable periodical, a very bad compliment, by telling us that we cannot understand an investigation of the subject, wherefore he "avoids all scientific observation as to the laws of friction," &c.; but I am sure that you, Mr. Editor, will join with me in removing the screen behind which he would thus shield himself from the liability of being called upon to prove his daring assertions. He must, or ought to know, that the majority of your readers are not "casual" but "professional" readers, who are perhaps as well skilled in investigation as "Vulcan" himself, and who are not accustomed to take statements for granted, because the person making them "fears his inability to make himself fully understood by casual readers." The case is simply stated; we have the force transferred from the piston rod to the crank pin by two different arrangements of machinery, the transfer in each case being attended with some loss, from the friction caused by the strain or pressure upon the gudgeons. The question is, then, what proportion does this loss bear, *ceteris paribus*, in the case of the Gorgon to that in the other or beam engine? This is perfectly ascertainable by mathematical analysis, and, in fact, in no other way, from the all but impossibility of having in practice other things alike in the two cases, which they must be, or extraneous causes will so affect the results as to render them perfectly inconclusive for the object in question. I will, therefore, with your permission, Mr. Editor, call upon "Vulcan" to show what ground he has for his assertion, by giving an investigation of this friction case; or if his "inability to make himself understood" arises from his ignorance of mathematics, he must get those by whom "he was assured" of the truth of his fact to help him out of his difficulty. If "Vulcan" does not furnish you with this statement, I will.

The third matter animadverted upon by "Vulcan" is what he calls Messrs. Seaward's statement, "that the consumption of fuel does not exceed 64 lb. per nominal horse power per hour." Now this statement is an entire and gratuitous fabrication. "Vulcan" must surely have been thinking of his ancient occupation in "Etna's fiery glow," and must have forged it for the occasion; for there is not a syllable about the Gorgon's consumption of fuel in the whole pamphlet, nor is the subject even alluded to throughout the work, except in one passage, page 24, where the saving of fuel is mentioned as one of the "great and paramount objects to be aimed at in the construction of steam engines for navigation." It is, indeed, added that "this system of engines is far superior in all the qualities above enumerated," but the saving of fuel named in the first paragraph seems to have been included in the other more by accident than design, for it is not even hinted at in any other portion of the work. Indeed, to have claimed for the direct system any material advantage over the common one on this score, would have been a downright absurdity; for what connection can a different arrangement of the rods and levers have with the consumption of fuel, except as regards the insignificant amount in which the difference of friction would affect it? and who, in their senses, would pretend that such was the fact? That the Gorgon engines do work with a much smaller proportionate consumption of fuel than many others, I can very readily believe; but whatever gain there is in this respect must be, of course, owing to improvements in the construction, which are independent of the direct action principle, and which Messrs. Seaward could just as well apply to beam engines as to the Gorgon's.

The introduction of the fuel question is, therefore, irrelevant, and only shows that "Vulcan" either can never have seen the pamphlet he pretends to review, or must be fixed in a much more discreditable alternative, which your readers will easily supply.

The remainder of "Vulcan's" paper consists of a series of statements which only show the limited information he had obtained upon the subjects he professed to treat of, and which will be sufficiently answered by noting down the following facts.

The speed of the Gorgon's engines, with 420 tons of coal on board and provisions for six months, is 19 strokes per minute; with 200 tons of coal, 21 strokes.

When the "Styx" was tried in the river, "with my lords and a large party on board," she had 260 tons of coal in the boxes, and 30 tons of water in the tanks, and the speed of her engines was 20 strokes per minute. "Vulcan" should, therefore, have placed less "confidence" in the information which led

* As a proof that errors in computing the weights of engines may easily arise, I can state that four pairs of beam engines, of 280 horse power each, were made in Scotland within the last three years, for the Government; each pair weighed about 60 tons more than the weight given by the makers to the Admiralty.

him to assert that she had only "coal enough for the trip, and no stores, and made 17 strokes per minute."*

It happens also, unfortunately for "Vulcan's" veracity, that the engines on the Gorgon principle have an arrangement to equalize their action, and balance the effect of the weight of the piston and its appendages; and that this moreover is not done by the means of weights upon the paddle wheels.

Those parts of the letter which treat of the "miserable inefficiency" of the "Government folks," who are stated to be so "far behind private knowledge and enterprise," and much of the same description, are worthy of a virulent scribe in an opposition newspaper: but as I should be very sorry to see your magazine made an arena for political discussion, "Vulcan" is very welcome, for me, to continue his tirade against the Government at his pleasure. He cannot deny that the Admiralty have given a decided preference to the direct form of engine, or he would doubtless be glad enough to do so; if he chooses to go upon another tack, and ascribe this line of conduct to their ignorance or their unjust partiality, it is of course with "my lords" that he has cause of quarrel, and not with the Gorgon engine.†

The "prophecy" with which the paper concludes will be upon record, and to it "Vulcan" may refer, in proof of his own sagacity and foresight, when he finds the Gorgon engines removed for inefficiency; but at present, while some of the vessels thus fitted are amongst the fastest sailers of their class, and while their superior adaptation for war purposes is proved by their services in actual engagement, (to which "Vulcan" bears such reluctant testimony,) we may safely conclude that the day of "Vulcan's" glorification as a true prophet will be yet far, far distant.

Bloomsbury,
Feb., 1842.

I am, Sir,
Yours obediently,
WILLIAM POLE.

MR. JOSIAH PARKES AND THE COUNT DE PAMBOUR.

SIR—In a letter inserted in your number for last October, Mr. Josiah Parkes has brought forward two grave charges against M. de Pambour: first, of "gross and lamentable ignorance of practical matters," founded upon a passage from this author's "New Theory of the Steam Engine;" secondly, of having misrepresented and falsified certain of Mr. Parkes's opinions and writings. The latter of these charges the Count has already sufficiently defended himself from, but the former he has left unnoticed, doubtless under the supposition that its groundlessness and absurdity must be so self-evident, as to render a formal refutation unnecessary. This may perhaps be the case, as far as those are concerned who are well acquainted with the subject on which the charge is founded; but it is probable there are many who, for want of information, may be inclined to construe the silence of Count de Pambour into an inability to deny the truth of the allegation, and I think it but common fairness that such should be shown the true state of the case. I should blush for English engineers, if there could not be found among us some liberal enough to defend from such ungenerous attacks as these, a distinguished foreigner who has, on connecting himself more immediately with our country, laudably devoted his time and talents to the advancement of our scientific knowledge.

M. de Pambour's passage is as follows:—"Under this circumstance (the use of the *cataract*), the engine does not evaporate the full quantity of water that its boiler would otherwise be capable of evaporating per minute." Mr. Parkes cites this to show the "gross ignorance" it displays, adding that "neither the Cornish, nor any other engineers ever, probably, imagined the *cataract* to exercise an influence over the *production of steam* in the boilers of their engines.

Now the following facts cannot, I am sure, be denied by any one at all acquainted with the working of Cornish engines.

1st. The use of the *cataract* determines the number of strokes to be made by the engine in any given time.

2nd. No steam being ever allowed, in Cornwall, to blow away at the safety valve, the quantity *produced* is necessarily only what is *used*.

3rd. The quantity used depends (*ceteris paribus*), upon the number of strokes made by the engine in a given time.

* See *Journal* for June 'ast, p. 210, Vol. IV.

† Since writing the above, it has come to my knowledge that an order for eight pairs of engines, upon the *direct action* principle, of 400 to 500 horse power each, has been decided upon by the "Government folks," and this with "Vulcan's" paper before their eyes!

4th. From which it must follow, if there be any meaning in words, that "the use of the *cataract*" does "exercise an influence over" the quantity of steam used, and consequently over "the production of steam in the boiler."

And of course when the *cataract* is so arranged as to cause the engine to make less than its maximum number of strokes per minute, (which is generally the actual state of things,) it must be evident that "under this circumstance the engine does not evaporate the full quantity of water that its boiler would otherwise be capable of evaporating per minute."

Mr. Parkes either knew these facts, or he did not. If he did, he lies under the imputation of having brought a charge against M. de Pambour which his reasoning powers must have told him, had he exercised them at all, he could not substantiate. If he did not, on which side does the "gross ignorance" lie? I can tell Mr. Parkes, that many persons of, perhaps, equal knowledge and skill with himself, are ready to plead guilty to an association with M. de Pambour in his "ignorance," if such it be.

But is Mr. Parkes himself perfectly immaculate, touching this *cataract*? He says, "The *cataract* is used for the purpose of opening the steam induction valve, and its value is appreciated as a means of effecting the influx of steam into the cylinder in the most instantaneous manner." Again, in his second paper on the percussive action of steam, published in the 3rd volume of the *Trans. Inst. C. E.*, (Note E, p. 430,) we find, "No apparatus for opening steam valves with rapidity, and, therefore, for letting loose the steam upon the piston of an engine, with the full velocity due to the difference of the elasticities existing in the boiler and in the cylinder, has yet been applied so effective as the *cataract*."

Now, as it happens, the *cataract* does not open the steam valve at all, except on the "House-that-Jack-built" principle. It only removes a catch, which lets fall a weight, which opens the valve, and effects, &c. The removal of the catch, which is all the *cataract* does, might be done just as well by the plug rod, or by hand, or by a thousand other contrivances, as by the *cataract*. It is the fall of the weight which effects the instantaneous opening; and therefore what merit can belong to the *cataract* on this score, it is not easy to see. It might as well be said to be valuable as a means of pumping the water from the mine, for it is quite as much instrumental to one as to the other.

It would have been well had Mr. Parkes removed this "beam from his own eye," before he began to find fault with the "mote" in M. de Pambour's.

I remain, Sir,
Yours, with respect,
LONDON,
Feb. 1842.
VINDICATOR.

ON THE FORCE OF FALLING BODIES, AND PILE-DRIVING.

SIR—In the *Journal* for last month, after the description of the "American Steam Pile-driving Machine" with which you favoured your readers, there are some judicious remarks on "the force of the blow given by the ram of a pile engine," and a table calculated from the formula $32\frac{1}{2} \sqrt{\frac{s}{16\frac{1}{2}}}$

for finding the velocity of a body falling from the height s , for the force in tons; the weight of the falling body being one ton. Now it appears to me, from want of defining an unit of force, and the force in tons therein gives, this table may be mistaken for a mere weight acting by pressure without any velocity, by persons not acquainted with the principles from which it is derived. Would it not, therefore, be well to define the unit of force, as you have taken it, to be the weight of the ram moving with a velocity of one foot per second? In page 255, Vol. II., July, 1839, concluding some remarks on this subject, I gave an example founded on the above principles, that is, taking the force used in driving the piles as the weight multiplied by the velocity, and comparing this with the weight of the superstructure, supposed also to be for the comparison a moving force.

In the *Mechanics' Magazine* for December 30, 1836, No. 175, a correspondent, in answer to a question on pile-driving, says the force of a ram falling from a height of 1½ inches is double its weight, and a correspondent, B, in your *Journal* for August, 1839, states from some experiments on a spring balance, that one-half the weight, falling with a velocity of ½ foot per second, is equal to the weight in effect; which is to say, that the whole weight moving with a velocity of ½ foot per second, produces an effect equal to twice the weight of the body. A body falling from the height 1½ inches acquires, after descending that height, a velocity of 2·6 feet per second. This would,

therefore give $\frac{1}{4}$ the less effect than B's experiment; or a velocity of 1.3 foot per second for a force equal to the weight, B's being a velocity of 4 inches, when the force equals the weight. The unit of force adopted by you lies between these. However, the truth is, little dependance can be placed in any comparison of this kind from want of analogy. But it appears to me the velocity $\frac{1}{4}$ foot per second given by B, produces an effect equal to the weight, and not its double, in his experiments.

Much good would result from persons registering and publishing the following data, when engaged in pile driving. *The piles*—timber, or other material, of which they are composed; weight and length; top and bottom sections; surface, whether rough or otherwise; weight and shape of shoeing; head, whether furzy or strapped. *Ground*—the different strata passed through, and their depths; the depth driven at each stroke, with the weight of the ram, and the height it fell from. These data would be of great benefit to the practical man, and would furnish materials to the theorist, who, in examinations of this nature, fails most often from not taking in all the circumstances, or from defective data.

Dundalk, Feb. 7, 1842.

JOHN NEVILLE.

SIR—It appears that a difference of opinion exists as to the amount of force with which a moving body strikes one at rest, as applied in the case of pile-driving. This difference of opinion probably arises from considering the force of impact as momentary; but a force of this description is quite imaginary, and cannot be assigned, unless we can comprehend infinity. Now if one man can raise one ton one foot high in one second, he can raise it two feet in two, &c. And whatever amount of force is expended in raising it will be measured by the free descent of the same weight through the same space, for if it were greater or less, the perpetual motion would be possible; therefore, on mechanical principles it must be equal. Hence a body raised to any given height may be considered as an accumulation of force equal to that which has been expended in raising it to that height; and the amount of this accumulation evidently includes two considerations—the amount of force employed, and the time of its employment. Now this accumulation being a certain definite amount of force, its expenditure will be regulated by the same laws as that which produced it. If, then, a certain amount of force be expended to raise a body one foot high, and this body fall through the same space, its momentum will be equal to the force which has been expended in raising it. Let it, after falling through this space, strike a body at rest, and by the force of impact carry it through an equal space, the whole amount of accumulated force being destroyed to effect this, the increments of the generating and destroying powers may be conceived as nearly equal, but not absolutely, for the descending body is supposed to descend through a greater space than it had been raised through, on account of its forcing the resisting body through some space, but as this is small and passed through slowly, it is of no practical moment. If, then, a body fall through 10, 20, or 30 feet, and carry a resisting body through $\frac{1}{10}$ of a foot, the force being destroyed to effect this, the force of impact will be proportional; that is, as often as $\frac{1}{10}$ of a foot is contained in 10, 20, or 30 feet, so will the weight of the descending body be to the force of impact.

That such is the law of impact is plain, for if a falling body could strike one having a velocity equal to its own in the same direction, the force of impact would be nothing; it would be simple contact. If the velocity of the body struck were less than its own, the force of impact would vary in proportion, and its limit is absolute fixedness without elasticity: in the first case it is nothing, and in the last it is infinite. The elasticity of all bodies is similar to that susceptibility of matter to be moved from place to place: it is a property of matter opposing resistance to force; and, as it relates to this question, it is nothing more.

Applying, then, these almost axiomatic truths to the case of pile-driving. Let a be the space the ram descends through, b the weight of the ram, s the space the pile is driven by a blow, and y the force of impact; then we have $\frac{ab}{s} = y$.

Now what practical deductions can be made from the preceding remarks?—the limit to pile-driving is the elasticity of the material driven. When the matter to be driven through is of such a nature as to resist the penetration of the pile with a greater force than is measured by the elasticity of the

material of the pile, further driving would be impossible. For instance, if the elasticity of the pile be $\frac{1}{2}$ of a foot, the force of impact being 600 tons, further driving would be impossible.

It is stated in your Journal for December last, that the force of impact 600 tons is the greatest blow that can be given by the pile engine imported from America. The weight of the ram is 16 cwt., the descent 30 feet.

Modifying the preceding formula, we have $\frac{ab}{y} = s$, and calculating from the above data, $\frac{30 \times 16}{600} = \frac{1}{12}$ of a foot.

Now if the limit of a pile engine's power be to strike a blow of 600 tons, it is because the effect is lost in the material struck. In the succeeding number of the *Journal* it is stated that the ability of this pile engine to strike with a force of 600 tons is an exaggeration; but if the above principles be correct, that assertion is a mistake.

It is a question of some practical importance to assign the weight of superstructure a pile will bear. The determination of y in the above equation is the answer. For instance; if the weight of the ram be one ton, the descent 20 feet, the distance the pile is driven by the blow half a foot, then $\frac{20 \times 1}{0.5} = 40$ tons, the weight that would be required to sink it; a less

amount would not. If the distance which the pile sinks at each blow be small, the elasticity must be taken into account; its effect is to diminish the result of each blow, that is, to make the divisor less than truth; the quotients would, therefore, be too large.

Objections might be made to what is here stated. In relation to elasticity, it might be said that the whole amount of force being communicated to the pile, it could not be lost; but its effect is to distribute the blow over a longer space of time. It might be also said of two rams of different weights, say one half that of the other, falling from the same height, that if the heavier was required to sink the pile, the other would not. If effects be proportional to their causes, the less would sink the pile half the distance of the other, and the quotient would then be the same.

I am, Sir,

Truly yours,

London, Feb. 10, 1842.

W. G.

SIR—I read with considerable interest, in your January No., a description of the American Steam Pile-driving Machine, and, having seen it myself, can bear testimony to its accuracy; but the table with which that description concludes is so manifestly erroneous, that attention should be called to it. The table assumes that a body of one ton weight, falling through one foot, would strike a pile or other object with a force equal to 8 tons, and the same weight falling through 16 feet would strike with a force equal to 32.1 tons; so that, although the weight had been raised through 16 times more space in the latter than in the former instance, and, of course 16 times the power expended to raise it, yet (according to the table,) the effect produced by striking a pile is only quadrupled: what then has become of the remaining 12 parts of the power exerted in raising the weight, seeing only 4 out of the 16 have been spent in striking the blow? Had the column headed "Force in tons for a ram weighing one ton" been "Acquired velocity in feet per second," it would have been about correct. Now the force exerted by a body in motion, when striking an object, as a pile, is as its weight and the square of its velocity, which has been long since demonstrated by Smeaton and other writers. Assuming, then, with the author of the table before-mentioned, that a ram of a ton weight, falling through a foot, would strike a pile with a force of 8 tons, and as it would have acquired a velocity of 8 feet per second, the same ram, falling through 16 feet, would have acquired a velocity of 32.1 feet per second, or 4 times the velocity in the former case; now $4^2 = 16$, and 16×8 tons = 128 tons, instead of 32.1 tons, as in the table.

There is, however, no authority for proving that a ram, falling through one foot, would strike a pile or other body with a force exactly equal to 8 times its own weight. I am inclined to consider its power much greater than this, though the precise amount it would exert as compared to a quiescent weight, I am not prepared to answer; indeed, it is a question undemonstrated by any writer I am acquainted with.

The laws relating to the comparative forces exerted by bodies in motion

of different weights and different velocities are well known, but the *absolute force exerted by any body in motion striking another body, as a pile, compared with a weight in a quiescent state*, is well worthy of investigation; though it may be doubted if the one can ever become the standard of measurement for the other. Any of your readers having time and opportunity to investigate this subject, would confer a benefit of great practical value.

I remain, Mr. Editor,
Yours very truly,
S. C. H.

Jan. 19, 1842.

[We reserve our remarks on the above communications until next month.
—EDITOR.]

MR. VIGNOLES' LECTURES ON CIVIL ENGINEERING, AT THE LONDON UNIVERSITY COLLEGE.

(Concluded from page 98.)

In the ensuing lectures he should endeavour to illustrate the following points—1st. The principles on which railways should be laid out under various circumstances of traffic, and topographical feature. 2nd. The comparison of different systems of inclinations or gradients. 3rd. The analysis of the advantages of various breadths or gauges. 4th. The illustration of the different modes of forming the railway proper, or upper works. 5th. The investigation and explanation of the great works of construction, as peculiarly found expedient in forming railways. 6th. The practice of framing estimates, and the necessary details connected therewith. 7th. The consideration of the various modes of working railways by animal and by mechanical power, locomotive and stationary. 8th. The inquiry into the working expenses and annual charge on railways; and, concluding with a summary lecture, in which the general features of the course will be given, and drawing such prominent inferences as might be most useful and interesting. The other branches of internal communication, as well as the various and numerous subjects connected with the theory and practice of a civil engineer, must be taken up on other occasions. Reserving, then, the elucidation of the details under the several preceding heads for the class room, he would proceed to make a few general remarks. Of these, the most prominent and most important, in his judgment, and most to be impressed upon the mind of those about to enter the profession of a civil engineer, was that connected with the great excess of actual expenditure in the construction of railways over estimates, for not only has that unfortunate, and almost invariable occurrence brought discredit on each concern so affected, but it has paralysed, and will long continue to paralyse, the most honest and well-grounded schemes for further internal communication in general, and of all improvements, the cost of which is dependent on the engineer; and though each case ought to be tried and judged on its own merits, the public confidence appears gone, and the capitalist observes with a sneer, "You engineers are all alike; we can trust none of you." Now, without shrinking from his own individual share of the odium thus cast upon the profession, as far as it may truly be deserved, the Professor denied the general and sweeping imputation, and he called on the directors of public companies, in justice to themselves, to their subscribers, to their own engineers, and to the public in general, to publish such details as would exonerate his profession, and leave it charged with no more than what was attributable to it. He called upon his brother engineers to follow this out, by furnishing their quota of information. Let the public in general know these details as matters of railway statistics of the highest interest—let the profession know them as matters of precedent of the most valuable kind—and let the capitalist be undeceived as to his present impressions of mistrust. Quite independent of any financial difficulties—quite independent of any standing orders or regulations of Parliament—a man might as well cry "mad dog" as talk of a new railway speculation, or a water-work, or, indeed, any public undertaking, where the function of profits is a certain known quantity, but dependent on estimates which are considered visionary, because "all engineers are alike in this respect." Let, then, the young engineer mark well the bitter lesson the oldest engineers are now learning—let them cause the most assiduous inquiry into the details—the most unremitting toil in gathering information—storing their minds, exercising their memories, practising their hand, and working out their calculations—let them remember that by working drawings, by models, and by every *a priori* means of unceasing investigation, they must "first and truly calculate the cost" of what in future life they may be called upon to undertake. If the matter be ever so trifling, they must not shrink from the truth, or attempt to disguise it from themselves, still less from their employers. Let them never have it said of them that they had whispered amongst themselves. "Oh! it will never do to tell the directors what the work will cost, or it will never be entered upon"—a remark which he had heard fall from an eminent

engineer; nor let them indulge in the vain hope of future fame, by taking as their text the observation attributed to another engineer of the very highest, and well-deserved, reputation—"A century hence there will be no one who will ask what this work cost, they will only inquire who did it."

He begged to repeat, then, what he stated at his first introductory lecture, that the constant maxim the young, as well as the old, engineer should keep before him is—"That the success of an engineer in this country of private enterprises and individual exertions, depends not upon the beauty or the cost of his constructions, or as mere works of art, but on their success as profitable and mercantile speculations." They must not suppose this to be an ignoble maxim; it must be followed out to its true results, and then they would find that prudence, caution, economy, judgment, and the highest intellectual gratification follow closely in its train; for, to apply the words of Mr. Booth, the intelligent secretary of the Liverpool and Manchester Railway, and one of the fathers of the modern railway system—"The contemplation of what is passing in England (alluding to the first cost of railways,) must not be without its lesson, for, in all countries, and under all circumstances, it is an object worthy of a statesman, to prevent the reckless waste of the national means, and to give a right direction to the public expenditure." And shall it be said that it is not equally worthy of an engineer? What are the aggregate subscriptions of associated and incorporated bodies of individuals but great portions of the "national means," which should not be wasted by the statesman or by the engineer? What are the monies invested in railways but a part, and, in the United Kingdom, a most important part, of the "public expenditure?" And is it not at once the duty, as it ought to be the pride, of an engineer, to give that expenditure a "right direction?" Let the maxim he had laid down be duly followed out, and that duty would be accomplished. The learned Professor continued, by stating that, even at the risk of having motives attributed which he should be unworthy of public or private estimation if he entertained for a moment, he would call the attention of the student to an instance of great expenditure on railways. The perfect completion in the manner contemplated of the internal communication by railway from London to the Sussex coast, a distance of little more than fifty miles, will amount, in the aggregate, to nearly four millions sterling. Is not that a reckless waste of the national means? Is that a right direction of public expenditure? Will not the public, in some way or other, pay for that?—the subscriber or the traveller, or both? To quote the words of an intelligent and experienced railway man—"With such results before us, would it not be almost criminal not to endeavour to secure the advantages of a better system?" The average cost of the railways in England has been very nearly £30,000 per mile. The cost of future lines must not be more than one-half of that sum, or it may be considered that there is an end to the extension of the railway system. The Professor stated that it would be his attempt to explain, in the course of his lectures, his ideas, that such a reduction in the expense might easily be made, and he would show that they were founded upon practical experience. The profession would be greatly aided, and the public vastly benefited, if the railway companies and their engineers would publish the detailed accounts he had asked for, to serve as a beacon, for which all would be very grateful; and it was his deliberate opinion and recommendation, that if they would not do so, Parliament ought to give the railway department of the Board of Trade powers to enforce such returns.

The total amount of capital invested in the railway speculations of this country is probably little short of £50,000,000, and the total extent of lines about 1700 miles—most of which are now completed. This may be said to be the creation of the last fifteen years. The total length of navigable canals in Great Britain is nearly 2500 miles; they were chiefly formed in the last 40 years of the preceding century. The capital invested in this branch was about £20,000,000, with an annual expense of about 50l. per mile. In addition to canals, there are about 1500 miles of navigable rivers. The turnpike-roads of England and Wales are stated, in official returns, to be nearly 20,000 miles in extent, executed at an expense of at least £20,000,000, and maintained at an expense of about £1,750,000 per annum, and all formed within little more than a century, exclusive of other highways, in length about 100,000 miles, with an annual expense of 12l. or 13l. per mile, or 75l. per mile for maintenance. The extent of executed railways in the United States of America appears to be about 4000 miles, executed within the last fifteen years, at a cost of about £8,000,000, or about £5000 per mile; most of them are single lines, and it is stated that the average net income has been about 5 per cent. per annum. The extent of railways in Belgium is now about 200 miles, executed at a cost of rather more than £1,500,000, or about £8000 per mile; most of these are single lines, and have all been executed within the last ten years.

The average annual expense of maintaining the railways of England (exclusive, of course, of moving power, carrying and managing establishments, &c.) appears to be from £200 to £300 per mile per double way; but on the Dublin and Kingstown Railway, where the system of longitudinal timbers for the upper works has been completely carried out, the same heads of expense are now reduced to less than 50l. per mile per annum, with a loco-

motive traffic over that railway as great, if not greater, than over any one in Great Britain. The average expense of the canal maintenance in this country seems to 50*l.* per mile per annum.

The Professor concluded by stating, that he would close his somewhat desultory discourse by calling attention to the fact, that the first elements of the amelioration of internal improvements, he would not say internal communication, which arose in this country, date from the period of the introduction of the Poor Laws into England, the effect of which has been to compel the rich to find employment for the poor, or to support them, and thus has been carried out the great principle of self-dependence, in separate districts, to work out their own improvements. Certain it is, that, from the passing of the Act of Elizabeth, which instituted a legal maintenance for the destitute, and, by making mendicancy a crime, swept the hordes of beggars, idlers, and sorners, from the face of the land, this country took a start, and, overtaking in improvement the other states of Europe, then far in advance of her, has since pursued that successful and continued march of amendment of her internal communication, which forms so remarkable a feature of England, proving her wisdom and proclaiming her prosperity. He begged that, with his previous cautions, the students would remember that the agent for the carrying out of such improvements, past and to come, has been, and he trusted long would continue to be, the civil engineer.

ON ARCHITECTURAL CRITICISM, &c.

TO MR. EAST, WITH A WORD TO H. S.

I SHALL be glad to be allowed to correct an error into which Mr. East has been led by the mystical signature of another correspondent, since he attributes to me a certain harsh voice which emanated from "Ditto." At the same time, I must acknowledge myself unable to comprehend the meaning of many of the hints, which is to be attributed to their not being written in a simple style, suited to the difficulty of the subject. That much of their obscurity arises from the manner of writing, I am led to infer from my total ignorance, after five careful perusals, of the meaning of the first paragraph addressed by mistake to me.

This will be, perhaps, the best opportunity for saying, that the whole of H. S.'s last communication might be readily inferred from the first; but they neither of them afford the explanation required, viz. how to account for the extension of precedent worship from Grecian to Gothic, and that a time when the classics have more than begun to find their proper level in every liberal education—when this age has the character for carrying utilitarianism and the study of science, if possible, to excess, and when general literary and scientific institutions are springing up in every direction.

If the cause stated by H. S. is correct, we are now only suffering from the effects of a past evil, and may be sure of a speedy reformation. As a proof of this, we need only refer to the programme of the University of London for the B.A. examination, where the classics form less than one-twentieth part of the course of study required. That there is a considerable movement in the architectural world in this direction, I may mention that the doctrine promulgated in the essay to which the medal of the Institute was awarded on the 28th of February last, was in unison with that of H. S., Ditto, and myself; and that it appeared to be received with general satisfaction.

J. L.

ACADEMY OF SCIENCES.

Jan. 24.—M. Pelouze read a report on a memoir communicated some weeks since to the Academy of Sciences at Berlin, by M. Magnus, on the experiments by M. Gay-Lussac and M. Rudberg to ascertain the dilatation of gas. M. Gay-Lussac had arrived at the conclusion, that what is called "the arithmetical co-efficient" of the number expressing the rate of dilatation, should be expressed by the decimal number .00375. This was the supposition that the volume of gas was measured under a constant pressure; but M. Rudberg had fixed the same co-efficient at .003646, by measuring the gas under a variable pressure. M. Magnus had repeated these experiments, and had arrived at results much nearer those of M. Rudberg than those of M. Gay-Lussac. This he attributed to a defect in mercury, as being unfit for exactly closing the apertures and joints of the vessels receiving the gas, notwithstanding that the use of mercury for these experiments was recommended by M. Biot in his *Traité de Physique*. M. Magnus had experimented on different gases and gaseous fluids, and had found the following co-efficients of dilatation: viz, air .003665, hydrogen .003656, carbonic acid .00369, and sulphuric acid .003856. It would appear doubtful whether the dilatability of

gas remains always constant, and whether it may not vary under various pressures.

Feb. 1.—M. Ebelmen read a memoir on the nature of the various vapours developed in smelting furnaces, as observed at different altitudes within the furnaces. The object of such researches was to determine the degree of heat at various points, and to devise means for the improved regulations of the fires. He has arrived at the following results.—1. The gaseous vapours, on coming out of a furnace heated by charcoal or wood, contain watery vapour, carbonic acid, and oxides of hydrogen and azote, but no carbonated hydrogen. At 6 or 8 feet below the mouth of the furnace the watery vapour is not found, and the proportion of oxide of carbon increases, while those of hydrogen and carbonic acid diminish, according as the observations are made lower and lower down in the furnace.—2. When coal is used jointly with wood for heating the furnace, the carbonization of the vapours takes place in an internal zone, and the water is expelled from the metal at a very low altitude. He found that the proportion of gas which traverses a certain zone of the furnace per minute, is greater according as it is further from the bottom of the furnace.

The Minister of Commerce communicated to the Academy some observations from the Industrial Society of Mulhausen, on the importance of adopting an unit of measure for the force of machines, considered not only in the power exerted, but in the time required. The Society observed, that the usual estimation of horse-power was not uniform, and proposed that the unit for France should be the force required to raise one kilogramme to the height of a metre in a second. To this unit they proposed that the name of *dyne*, from the Greek root, signifying "moving force," should be applied, and then that it should be compounded with Greek and Latin words, in the same way as the metre, the gramme, &c. Thus the *kilodyne* would signify a thousand times this unit, and the *millidyne* would signify the thousandth part of the same unit.

M. Arago read a communication from M. Rusiger, a German geologist, on certain geometrical observations, made in order to ascertain the relative altitudes of the Dead Sea, in Palestine and the Mediterranean. It appeared not only that the surface of the Dead Sea was 219 toises, or about 1,314 feet lower than that of the Mediterranean, but also, from the geological phenomena observed on its shores, that the formation of the basin in which it lies was antecedent to all historic epochs. Hence the supposition that the sea was formed by the sinking of the plain on which the cities of the Pentapolis (Sodom, Gomorrah, &c.) were situate, is incorrect. M. Arago added, that the observations of M. Bertou, a French engineer, made the depression of the Dead Sea below the Mediterranean 419 metres, or 1,374 English feet.

Feb. 7.—M. Arago gave an account of two memoirs by Mr. Dove, "On the Phenomena of Chemical Induction." An electrical current causes, in a mass of iron placed near it, two kinds of phenomena—one corresponding to magnetism, the other to dynamical electricity. The author of these memoirs announced that he had succeeded in separating the two classes of action, by giving them different degrees of relative intensity; and he had shown the magnetic action to exist in substances where its presence had not been suspected.

M. Vallé, colour-dealer, submitted to the notice of the members some specimens of *canvas for oil-painting*, covered with a substance intended to preserve the colours laid on it from all effects of moisture.

Feb. 14.—A communication was read from M. Combes, on a supposed cause of the contortions of the metallic tube in the bore of the well of Grenelle.

Extract of a memoir, by M. Bessell, on a phenomenon of atmospheric light, which appeared to be the reflection of a fire on the earth from the surfaces of clouds, which were probably frozen.

A note was read from M. Mallet, of St. Quentin, upon some further improvements in the purification of gas. He had succeeded in depriving gas, not only of its ammonia and its sulph-hydric acid, but also of its empyreumatic products and of its naphthaline. The gas, thus purified, was found to retain only a very slight empyreumatic smell, very different from the fetid odour which it commonly possessed.

M. Nothomb informed the Academy that he had found considerable advantage, in photographic operations, resulting from the use of protochloride of mercury, instead of pure mercury, as originally used by M. Daguerre.

Feb. 21.—Some curious experiments were mentioned as having been lately made by Capt. Bailly, of the engineers, on an artesian well at Lille, which had exhibited some remarkable phenomena of intermission in the discharge of the water. M. Bailly had proved that these intermissions corresponded with the tides at Dunkirk.

M. Arago read a communication from Mr. Nasmyth, an English engineer, stating that it had been observed, on several lines of railroads in England, that the rails never rusted when they were traversed by wagons going always in the same direction; but that when they served for wagons going in opposite directions, as in the case of a single line of rails, they became rusted very soon.

Feb. 28.—M. Arago gave an account of the proceedings of the commission on the question of inventing either an indelible ink, or else a "paper of safety," in order to prevent forgeries. It appeared that the invention of an indelible ink was given up, as insufficient for the purpose, and that the efforts of competitors for the premium of 36,000 fr. offered by Government in 1836, were now directed to the making of the safety paper. It had been proposed to cover the paper with a kind of vignette, or tool-work, in an ink that should be in part liable to be effaced; so that if any attempts should be made to alter the writing or printing on such paper, the vignette work would

WEIGHTS AND MEASURES.

At one of the evening meetings of the Professors of University College, Mr. De Morgan discussed the recent report of the commission on the new standard weights and measures. The imperial standard yard and bushel, constructed in pursuance of the statute of 1826, were destroyed by the conflagration of the Houses of Parliament, and a committee of men of science was appointed to consider the best mode of restoration. The statute had directed their restoration by what is called a natural method—the measure of the length of a pendulum swinging seconds in the latitude of London, under certain conditions, but the progress of experiment has induced the commission to repudiate that method and to recommend the adoption of the old plan of having standards constructed. It is to be observed that the experiments of Kater, Baily, Bessel, and others, have of late years shown, that as regards the pendulum, the amount of correction due for the pressure of the atmosphere, level of the sea, terrestrial disturbance, and other causes, is far from being ascertained. Professor De Morgan, indeed, intimated strong grounds for the non-existence of any such thing as a natural standard. Fortunately, it has happened that the Royal Astronomical Society possesses a copy of the standard yard, and from this the Commissioners propose that the new standards should be restored. Speaking of standards, Mr. Baily reported to the Astronomical Society that the old standard yard, made in the time of Queen Elizabeth, and preserved at the Exchequer, was in existence four years ago, when he saw it. It is described as a most disgraceful specimen of workmanship, being little better than a common kitchen poker, filed at each end, while at some distant period it had been broken in the middle, and the point dove-tailed and left loose, so as to bend like a pair of tongs. Of this implement copies used to be furnished by the officers of the Exchequer to foreign men of science, accompanied with a parchment certificate, on which the stamp duties were four guineas, besides official fees—a circumstance truly designated as productive of national disgrace. Several copies of the new standard measures are recommended by the Commissioners to be preserved for use in different parts of the country, and four sets to be imbedded for preservation in a stone in the foundations of the new Houses of Parliament, and only to be removed by the authority of the legislature. The other recommendations are—the abolition of the troy pound; the establishment of a new long measure; and the introduction of a decimal coinage. The Commissioners propose that a measure of one thousand yards should be authorized to be used, and should be adopted by Government in the mensuration of public works, &c. This is not proposed, for the present, to supersede the mile, but to work concurrently with it; and they suggest that the new measure should be called a milyard, a name rightly designated by the Professor as a barbarous mixture of Latin and English. He observed that the old English mode of combination is exemplified in the word furlong, which signifies the forty long, that is, forty poles long; so he would call the new measure a thousand long, which would, like other words, ultimately be abridged by the public. He remarked that we have already a decimal system, which has been introduced without the authority of Magna Charta by the example of one man, and which has now become engrafted on the whole system of our landed property—he alluded to the surveyor's chain of one hundred links, the extension of which as the standard measure of length he much wished to advocate. The Professor did not say how he would apply this, but as it is a subject in which our professional readers should interest themselves, we shall make some remarks upon it. We have already the chain, and furlong of ten chains; the next step in ascent is a new mile of ten furlongs, being one old mile and a quarter. This new mile would be nearly equal to two French kilometres, or as 2200 yards to 2187.22, or a difference of only 12.77 yards, or little more than one half per cent.* Descending from the chain, we should have a fathom of ten links, (6.6 ft.) being nearly the same as the new French toise, or as 2.0116436 to 2½, and only six inches more than the common fathom. The tenth of the new fathom, or toise, is the link of .66 of a foot, or nearly two-thirds of the present foot, and the tenth of this link or foot will give a new inch of about four-fifths of the present inch. Were our professional readers to take this subject in hand, and give it their support, we have little doubt that, either with or without Government aid, they would be able to carry out the chain standard. At the same time, we must call their attention to the serious evil which will accrue to them from the adoption of the milyard or thousand-long, which will not work well with the chain, and will create the greatest difficulty in all land measurements, and much confusion as to landed property. The first step would be the adoption by the naval service and by engineers, architects, and surveyors, of the fathom of ten links, which will prepare the way for its general adoption. The close resemblance between the chain measure and the French metre system is a further recommendation.

"The first step" says Professor de Morgan, "to decimal weights and measures is a decimal coinage, a system which the Commissioners have recommended generally, without laying down any particular plan." Mr. De

* This new mile would be 55.6 to the degree, instead of 69½, and would be to the Irish mile as 2200 to 2240.

Morgan's proposition is for a gradual introduction of the plan. He would, in the first instance, without any Act of Parliament, introduce a two-shilling piece, and withdraw the half-crown. To this two-shilling piece, it would be advantageous to assimilate to the East India Company's rupee, so as to make that important branch of our currency uniform with that of the seat of empire. He would then coin a piece of twopence-halfpenny, five of which would make a shilling and a halfpenny, and ten a two-shilling piece and a penny. The working of this would be, he considers, to produce practically the fifth of a shilling; for the public would, in most dealings, make the tradesman give them the advantage of the halfpenny or penny, and so in the end decimalize the two-shilling piece. He would then, by Act of Parliament, reduce the nominal value of the copper coinage four per cent., by which the farthing would become the thousandth part of a pound, and the decimal system be established.

STEAM NAVIGATION.

The West India Mail Steam Packet Company's Steam Ship "Trent."—We have been much gratified by our visit to this vessel, which left the Thames on the 27th of February. The machinery is by Messrs. Miller, Ravenhill & Co., and in every particular of its structure, proportionment, and disposition, manifests the most eminent engineering ability. There is not a detail in the whole of the machinery which is not calculated to excite the conviction that its specific character is the result of the study of an able mechanician, and that its adoption has been the consequence of mature reflection, not of an inconsiderate reference to existing modes of construction. The power of these engines is 430 horses; the diameter of the cylinder 74 inches; the length of the stroke 7 feet. The condenser, the cylinder bottom, the air-pump bottom, and the support for the main centre, are cast upon the foundation plate. The condenser is beneath the foundation plate, so that the main centre does not pass through it as it does in many engines. The framing has been constructed with reference only to the strains to which it will be subjected, and without any attempt at what is termed architectural decoration; with one exception, where it could not be effected, all the principal joints are metallic, that is, the metallic surfaces of the joints are planed, and so accurately fitted as to be perfectly tight without the aid of rust, or without any substance interposed except a little red lead. With a view to increased durability brass and copper have been introduced with an unsparing hand, many of the parts which are made of iron in ordinary engines being of brass or copper in these.

The performance of the engines attests the skill and care concerned in their production. They work with great smoothness and efficiency, and with a consumption of only 16 cwt. of coals per hour. With a pressure in the boiler of only 3.78 lbs. per square inch, the mean pressure on the piston is 14.17 lbs. per square inch. The difference between the vacuum in the condenser and the vacuum is only .28 lbs. of pressure per square inch.

We are unable to enter into further details respecting this machinery at present, but we purpose next month to give a description of the machinery of the *Isis*, which started on Tuesday, 29th ult., also by Messrs. Miller, when we shall enter more fully into the merits of Messrs. Miller's arrangements, and hope to adduce good reason for our commendation.

MISCELLANEA.

INLAID ORNAMENTAL TILES.—Last month we noticed a work that had just been published, containing numerous examples of encaustic or inlaid tiles, selected from various ecclesiastical buildings in England: we are now enabled to announce that Messrs. Wyatt, Parker, and Co. have commenced the manufacture of these tiles. From the specimens sent us, we can judge that they will be found to be very durable, and far less porous than the ancient tiles, and will form an admirable addition to the architecture of our churches, by using them instead of stone or deal floors, in the side and centre aisles, and such parts as are not covered with seats; they may also, with equal taste, be used for lining the walls. The specimens now before us are made from Staffordshire clay of a dark red colour, and inlaid with yellow. Messrs. Wyatt have also sent us some specimens of pottery of an hexagonal shape, of various colours, for paving halls, dairies, &c., or for lining the latter; likewise small squares, from half an inch to an inch square for mosaic pavement. A variety of specimens of paving may be seen at Messrs. Wyatt's works.

Continental Machinery.—We perceive in the *Eco della Borsa* of Milan, that extensive mills have been erected in Lombardy for spinning of cotton and silk, and that there is now being added another on a very extensive scale, for spinning and weaving of flax and hemp. It is undertaken by a public company, at the head of which is S. Battaglia the banker. It is situated near Milan, on the Adda. We observe that the entire direction of projecting and executing this new concern was confided in 1840 to Mr. Albano, C. E., of London: it is stated to be the most complete mill in all its details that has ever been erected. The powerful water wheel, and the mill gear for driving the spinning machinery, are of a superior description, and were made in this country, by the celebrated firm of W. Fairbairn and Co., of Manchester. In consequence of the prohibitory character of our export laws, the spinning machinery is to be made in Belgium, although the Company was most desirous that it should be made in England. Here is another example of the ruinous

Effects being produced upon the country, through the absurd prohibitory laws. We thus see that an order of several thousand pounds is taken out of our hands. How long this is to last it is impossible to say.

A Public Park at Liverpool.—The Liverpool papers state, that Mr. R. V. Yates has purchased from the Earl of Sefton forty-three acres in Toxteth Park, two-thirds of which are to be laid out for a park for the use of the public, and the remaining third is to be appropriated to sites for villas. The noble lord receives £1100 per acre, so that the purchase money for the whole will exceed £47,000. The land is beautifully situated, commanding fine views in every direction.

Steam Engines in Belgium.—It is estimated that there are now at work in Belgium 1300 steam-engines, with a total power of 33,100 horses.—*Galignani.*

Atmospheric Railway.—The report on this subject of Sir F. Smith, R.E. and Prof. Barlow, has been presented to Parliament. The summary of their opinions is thus given:—"1. That we consider the principle of atmospheric propulsion to be established, and that the economy of working increases with the length and diameter of the tube. 2. That the expense of the formation of the line in cuttings, embankments, bridges, tunnels, and rails, will be very little less than for equal lengths of a railway to be worked by locomotive engines, but that the total cost of the works will much greater, owing to the expense of providing and laying the atmospheric tube, and erecting the stationary engines. 3. That the expense of working a line on this principle, on which trains are frequently passing, will be less than working by locomotive engines, and that the saving thus effected will, in some cases, more than compensate for the additional outlay; but it will be the reverse on lines of unfrequent trains. However, there are many items of expense of which we have no knowledge and can form no opinion, such as the wear and tear of pistons, valves, &c.; on these further experience is needed. 4. That with proper means of disengaging the train from the piston in cases of emergency, we consider this principle as regards safety equal to that appertaining to rope machinery. There appear, however, some practical difficulties in regard to junctions, crossings, sidings, and stoppages at road stations, which may make this system of less general application."

Brick-making, &c.—A discovery has been made by Mr. R. Prosser of Birmingham, which bids fair to be attended with important results to the interests of architecture. The novelty of Mr. Prosser's process consists in the clay being dried, ground to powder, and submitted to pressure in metallic moulds, until the particles cohere together. As there is no water in combination with the clay, no drying process is necessary; consequently the articles made by this method are ready to be fired or burned as soon as they leave the machine. Owing to the great pressure required to cause the particles of clay to cohere together, the articles made by this press have greater density than those made in the ordinary way; they are also less porous, and not subject to decay in wet or frost. In addition to these advantages, any architectural device may be impressed upon the clay, which, when burnt, will retain all the sharpness of the original, however elaborately finished. By this process bricks may be made in all weathers, and with greater economy than by any other plan known at present. The brick-press is worked by hydraulic pumps, giving about 300 tons pressure, thus producing the adhesion and cohesion. The machine delivers the brick (four at a time in the present machine) ready at that instant for the kiln, requiring no exposure to the atmosphere to dry. The whole operation, from the time of putting the powdered clay into the machine to the delivery of the brick, occupies about half a minute. Machinery might readily be constructed to produce bricks fifty a minute.—*Daily paper.*

Architectural honours.—We are happy to announce that Mr. Cockerill has been elected a foreign member of the *Académie des Beaux Arts*, in the room of the late M. Antolini of Milan, and that Mr. Barry has been elected a member of the Royal Academy, in the room of the late Sir David Wilkie, an appointment that will give the greatest satisfaction to every architect: we have now three architects in the Academy.

M. Antolini.—The following notice of this eminent architect, who lately died in Italy, appeared in the *Art Union*:—"Cavalier Gio Antonio Antolini was born in 1754, of a respectable family at Castel Bolognese: he studied at Bologna, and there took a degree as an architect and engineer. He was called to Rome for the works on the Pontine Marshes, and at Rome he studied deeply the remains of antiquity, and published 'Illustrations of the Temple of Hercules at Cori.' He then went to Milan, where he designed the plan of the Forum Bonaparte. He was afterwards named to two chairs, those of Architecture in the Academy, and of Geognosy in the University of Bologna; and he was subsequently elected a member of many learned bodies, including the Institute of France. He held many honourable public appointments, and executed many works for the Italian government as well as for individuals; he was also employed in foreign labours, latterly for the Viceroy of Egypt. He has left, it is said, in his son Philip Antolini, the heir of his talents as well as of his name. He has published the following works, besides the above-mentioned:—"The Ruins of Velleja in the Picentino;" "The Temple of Minerva in Assisi;" confronted with the plates of Andrea Palladio; "Elementary Ideas of Civil Architecture;" "Notes to the Treatise of Architecture by Milizia."

Thames Tunnel.—We are happy to hear that this work is now past all danger, and that within a few months it will be open to the public as a thoroughfare. The entire brick structure of the Tunnel, uniting the two opposite shores, is now wholly completed.

Paris.—To the already numerous buildings which have been recently erected for the embellishment of the French metropolis, a new palace is to be added, for the Archbishop, on the Quai Napoleon, facing the Hôtel de Ville: it is to be in unison with the Cathedral of Notre Dame. The beautiful turret and other fragments of the Hôtel de la Tremouille, whose demolition excited so much interest, are to be appropriated to the sacred edifice.—The colossal statue of "Immortality" by M. Cortot is about to be cast, and placed on the dome of the Pantheon.

Monument of Napoleon.—The French newspapers announce that the Government have ordered that the monument to Napoleon shall be executed according to the plan recommended by the Commission appointed to examine the competition drawings and models, who reported that none of the models were entirely satisfactory, and recommend to be erected a sarcophagus of granite or porphyry, of a severe and noble form, placed on a pedestal of an indestructible material, which appears to the Commission to be the most suitable monument which can be raised to contain the ashes of Napoleon. It should convey the idea of eternity, and that the remains of the great man are safe from the vicissitudes and accidents of time. It ought to be constructed in such a manner as to survive the destruction of the church which contains it, and the fall of the dome, and it should be impervious to fire. As to the objection to the plan of a crypt, that it is exposed to damp and to inundations, it is not true; the foundation of the Invalides is many metres above the highest waters, and its vaults are remarkably dry. The excavation of the crypt besides, renders any other appropriation of the dome impossible; it must remain for ever sacred to the ashes of Napoleon. The Commission further expresses the opinion that within the inclosure of the Invalides, but without the church, and quite apart from the tomb, an equestrian statue of the Emperor should be erected. It further expresses the wish that this statue should be represented in the Imperial costume, to mark that Napoleon is honoured not less as a statesman and legislator, than as a warrior. The tomb within the church—nothing, in the presence of God; without—the statue—glory, in the sight of men. It limits itself to recommending this programme—an open crypt within the Church of the Invalides, an equestrian statue of the Emperor without. The French Government have appointed Messrs. Visconti and Marochetti to carry out the design; the first for the architectural and the second for the sculptural.

Hamburgh.—The New Exchange, which has been building during the last five years under the direction of the architect Wimmel, is now finished. The noble simplicity of this edifice renders it one of the greatest ornaments of the city.

Munich.—Swankhaler has been selected by the King of Bavaria to execute a great work, to be called the "Pantheon of Bavaria." It is to be erected on the hill of St. Theresa, near Munich. On the summit is to be placed a bronze statue of Bavaria, fifty-nine feet in height, resting on a lion twenty-five feet high. Around, under open colonnades, are to be placed statues of the illustrious men of Bavaria.

Russia.—A monument of cast iron in the Byzantine style has been erected at Smolensk, by imperial command, in memory of the battles of 1812. It is placed on the Parade Platz, opposite the King's bastion, which was the point where the battle raged most furiously on the 5th of August, 1812. The inauguration took place on the 5th of November last.

Warsaw.—A monument of cast iron has been erected on the Saxon Platz, by command of the Emperor of Russia, to the memory of the seven Poles who fell in defence of the Russian power on the 29th of November, 1830. The plan is that of the architect Corazzi, chosen from among ten competitors. The octagonal base is of native marble; eight bronze lions support an iron pedestal, above which are four eagles of gilt bronze, their wings outspread; a shield is on the breast of each, on which is inscribed a map of Poland; from the pedestal springs an obelisk of cast iron. The octagonal marble base is 30 feet in diameter; the pedestal 8½ feet in height by 10 in diameter; the obelisk 25 feet in height, 6 in diameter at the base, and 4 at the top. The iron and bronze were both cast in Warsaw.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 25TH FEBRUARY, TO 23RD MARCH, 1842.

Six Months allowed for Enrolment.

WILLIAM NEWTON, of the Office for Patents, 66, Chancery-lane, in the county of Middlesex, civil engineer, for "improvements in regulating the flow of air and gaseous fluids." A communication.—Sealed February 25.

OSBORNE REYNOLDS, of Belfast, Ireland, clerk, for "improvements in covering streets, roads, and other ways, with wood; and also in the means of enabling horses and other animals to pass over such roads and other slippery surfaces, with greater safety than heretofore."—Feb. 25.

JOHN BIRKBY, of Upper Rawfold, card manufacturer, for "improvements in the manufacture of wire cards."—Feb. 25.

WILLIAM SAUNDERS, of Brighton, Sussex, gent., for "improvements in apparatus employed in roasting and baking animal food."—Feb. 25.

SAMUEL MORAND, of Manchester, merchant, for "improvements in machinery or apparatus for stretching fabrics."—Feb. 26.

BENJAMIN GILLOT, of Great Saffron Hill, cutler, for "improvements in heating and ventilating."—Feb. 26.

MARC LA RIVIERE, of London Fields, Hackney, gent., for "improvements in the machinery for figure weaving in silk and other fabrics."—March 1.

THOMAS SMITH, of Northampton, plumber, for "an improvement or improvements in water closets."—March 1.

GEORGE CARTER HASLER, of Birmingham, jeweller and toy-maker, for "improvements in the tops of scent bottles."—March 3.

EDWARD SLAUGHTER, of Bristol, engineer, for "improvements in the construction of iron wheels for railway and other carriages."—March 4.

JAMES CLEMENTS, of Liverpool, manufacturer of toys, for "improvements in composition for ornamenting glass and picture frames, and articles for

interior and other decorations; also for the manufacture of toys and other fancy articles."—March 4.

WILLIAM PALMER, of Sutton-street, Clerkenwell, manufacturer, for "improvements in the construction of hinges."—March 4.

HENRY BARRON RODWAY, of Birmingham, wine merchant, for "improvements in the manufacture of horse-shoes."—March 7.

THOMAS HENRY RUSSELL, of Wednesbury, Staffordshire, iron tube manufacturer, and CORNELIUS WHITEHOUSE, of the same place, for "improvements in the manufacture of welded iron tubing."—March 7.

WILLIAM NEWTON, of the Office for Patents, 66, Chancery Lane, Middlesex, civil engineer, for "an improved machine or apparatus for weighing various kinds of articles or goods." A communication.—March 7.

THOMAS HEDLEY, of Newcastle-upon-Tyne, gent., and CUTBERT RODHAM, of Gateshead, Durham, millwright, for "an improved apparatus for purifying the smoke, gases, and other noxious vapours, arising from certain fires, stoves, and furnaces."—March 8.

WILLIAM CATFORD, of Chard, Somersetshire, mechanic, for "improvements in machinery or apparatus, for making or manufacturing lace or other netted fabrics."—March 8.

HENRY SMITH, of Liverpool, engineer, for "improvements in the construction of wheels and breaks for carriages."—March 10.

RICHARD BEARD, of Earl-street, Blackfriars, gent., for "improvements in the means of obtaining likenesses and representations of nature and of other objects."—March 10.

WILLIAM EDWARD NEWTON, of the Office for Patents, 66, Chancery-lane, Middlesex, civil engineer, for "improvements in boilers, furnaces, and steam-engines." A communication.—March 10.

CHARLES WILLIAM FIRCHILD, of Woley Park, Northfield, Worcestershire, farmer, for "an improved propelling apparatus, for marine and other purposes."—March 14.

REUBEN PARTRIDGE, of Cowper-street, Finsbury, engineer, for "improvements in machinery or apparatus for splitting and shaping wood into splints, for the manufacture of matches and other similar forms."—March 14.

ALFRED GREEN, of Sheffield, surgical instrument maker, for "improvements in trusses or surgical bandages."—March 15.

EDWIN WARD TRENT, of Old Ford, Bow, rope maker, for "an improved mode of preparing oakum and other fibrous substances, for caulking ships and other vessels."—March 21.

SYDNEY JESSOP, of Sheffield, merchant, for "an improved mode of preparing wrought iron, intended for wheel tires, rails, and certain other articles."—March 21.

ZACHARIAH PARKES, of Birmingham, manufacturer, for "an improved mode of preparing wrought iron, intended for wheel tires, rails, and certain other articles."—March 21.

JOHN CLAY, of Cottingham, near Hull, Yorkshire, and FREDERICK ROSENBORG, of Sculcoates, Yorkshire, gent., for "improvements in arranging and setting up types for printing."—March 21.

WILLIAM HANCOCK, the Younger, of Amwell-street, gent., for "improvements in combs and brushes."—March 21.

EDWARD JOHN DENT, of No. 82, Strand, chronometer maker, for "improvements in chronometers and other time-keepers."—March 21.

WILLIAM BROCKEDON, of Queen-square, Middlesex, gent., for "improvements in manufacturing fibrous materials, for the cores of stoppers, to be coated with india-rubber, and used for stopping bottles and other vessels."—March 21.

JOHN HAUGHTON, of Liverpool, clerk, for "improvements in the method of affixing certain labels."—March 21.

WILLIAM PALMER, of Sutton-street, Clerkenwell, manufacturer, for "improvements in the manufacture and preparation of pills, and some other articles of a medicinal or remedial nature."—March 21.

MARK FREEMAN, of Sutton Common, gent., for "improvements in the construction of inkstands."—March 21.

ROBERT HAZARD, of Clifton, Somerset, confectioner, for "improvements in apparatus for heating public and private buildings."—March 21.

MOSES SPERRY BEACH, of Norfolk-street, Strand, printer, for "improvements in machinery used for printing with type, and in the construction of type for printing." A communication.—March 23.

TO CORRESPONDENTS.

Seyton.—The plan for reversing engines is ingenious, but the drawing is badly executed, and the description contains several errors. The allegation that lap is inapplicable to a slide valve worked by a fast eccentric (i.e. an eccentric fast on the shaft), is erroneous. What is meant by "the expansion valves are constructed to cut off the steam till the end of the stroke?" If Seyton forwards us a proper drawing of his contrivance, such as a mechanic might execute the work from, we will consider of the propriety of inserting it in the next month's number. We are always desirous to encourage the efforts of young mechanics, and in the contrivance of Seyton we can discern much ingenuity and considerable promise.

Amicus Machinarum.—The project advocated by this correspondent of placing the air pump of a steam engine in the middle of the cylinder, is one

of the wildest we have met with for many a day. The annular cylinder of Messrs. Maudslay is objectionable enough as it stands, even in the skilful hands of that eminent firm; but with our correspondent's improvement, this description of engine would have the merit of being the very worst at present existent.

The central cylinder in Messrs. Maudslay's arrangement is used for the purpose of obtaining a long connecting rod. This object our correspondent seems to appreciate very lightly, for he employs a short connecting rod of the Gorgon species, and into the vacant hole in the middle of the cylinder he places his air pump; the pump having the same length of stroke as the cylinder. It is the aim of engineers in general to keep the cylinder hot, but this gentleman has so far surmounted the prejudices of existing systems, that he has introduced a pump into the middle of the cylinder, for the purpose of keeping the cylinder cool. We are at a loss to imagine in what idea this crotchety could have originated; but we recommend our correspondent to forego all attempt at improvement until he has learned something of engines of the unimproved construction.

It is disadvantageous to make the stroke of the air pump equal to that of the cylinder. The valves are sure to strike very hard and wear themselves out very soon, when the bucket moves with a great speed.

Our correspondent's drawing is very neatly and, we may add, skilfully executed. We should be glad to find this peculiarity more common than it now is.

A Constant Reader, Greenock, asks us whether we approve of an improvement he has devised in the glass gauge tubes of marine boilers. We reply, decidedly not, unless it be our correspondent's object to render a very simple and excellent arrangement inefficacious. "In the boilers of marine engines," our correspondent observes, "a great agitation of the water often takes place from the ebullition, and at such times it is difficult, on account of the agitation of the water in the glass tube, to ascertain the real level of the water in the boiler." Our correspondent, therefore, proposes to lead small copper pipes from each extremity of the glass tube, where it communicates with the interior of the boiler, to a point considerably beneath the ordinary water level. Let us suppose this done; what will be the effect? When the water is first introduced into the boiler, it will rise in the two pipes connected to the opposite extremities of the glass tube, until its further ascent is resisted by the elasticity of the air shut within the pipes and glass tube. If this air be allowed to remain, no water will enter the glass tube at all; but the air may be allowed to escape by unscrewing the top of the socket which holds the tube. The water will then assume the same level in the tube that it possesses within the boiler. Suppose now that steam is got up, and the lower cock attached to the glass tube opened, so as to let some of the water escape, as is the usual practice, to make sure that there is no stoppage in the pipes. Upon shutting the cock, the glass tube will fill with water, not steam; nor is there any possible mode by which steam could obtain access to the upper part of the tube. Even if steam were, by any supernatural method, introduced, it would soon be condensed, by the escape of heat from the glass tube and brass socket, and the glass tube would refill with water. A glass gauge tube, therefore, if constructed after our correspondent's improvements, would be altogether inoperative as an indicator of the water level. The agitation in the tube our correspondent complains of may be stopped by nearly closing the cocks which sentinel the communications between the top and bottom of the glass tube and the boiler. It is beneficial also to lead a small copper pipe within the boiler, from the upper glass tube communication to a point some feet above the average water level, and another from the under passage communicating with the glass tube to a point some feet beneath the average water level. The sketches which accompany our correspondent's paper are of the rudest description, and his description of the construction and operation of the glass gauge tubes in common use is erroneous in several particulars. He shows no cock in the upper or steam communication between the glass tube and the boiler, so that if the glass tube be accidentally broken—and that, in steam vessels, is not an unfrequent occurrence—the steam cannot be shut off, but escapes full bore into the engine-house. He says also that by opening the lower cock, and allowing the water to rush out, any little obstruction in the tube is cleared away. But if the water be allowed to rush from the lower cock from the boiler, it will not enter the glass tube at all, and, therefore, cannot be instrumental in cleaning it. It is by no means uncommon for glass gauge tubes to become so dirty, especially if the water be muddy, that it is difficult to see the height of the water in them. They are cleaned by being blown through with the steam, not by the water.

"A Workman" on the Skew Arch.—This is a paper investigating the method of finding by calculation what Mr. Buck terms the focus of a skew bridge and the eccentricity of its face. The problem has been previously solved by Buck in his Treatise, by W. H. Barlow, C. E. & A. Journal, No. 48, and, we think, by P. Nicholson, in his "Railway Masonry." The first part of the paper we cannot clearly understand, owing to the loose way in which it is expressed. He certainly, however, brings out no result from it. In the second part, relating to the eccentricity, he neglects, in consequence of its practical unimportance, the sine of a very small angle, and by that means brings out a formula which is certainly simpler than Buck's. Looking, however, to what others have written on the same subject, and considering the manner in which the paper is written, we cannot insert it in its present form; but as the writer evidently understands the subject, we shall be happy to insert it if he will make it more elementary, and more precise and accurate in its expression.

We have received several other communications, which we are obliged to postpone, together with reports of Lectures at King's College and London University.

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, III, and IV, may be had, bound in cloth, price £1 each Volume.

PROTESTANTISM AND ART.

1. *De Protestantismo Artibus haud Infesto. Scripsit CAROLUS GRU-NEISEN. Stuttgartiæ et Tubingæ, 1839, 4to.*

2. *Der Protestantische Gottesdienst, und die Kunst, 1840.*

NOTHING, we conceive, but an over-scrupulous horror of the abominations of the church of Rome has induced the reformed church to repudiate, together with the creed and ritual of Rome, the services of those arts which, when legitimately employed to such end, enhance the decorum and solemnity of religious worship, rendering it more impressive. A very laudable indignation at the abuse of art in the theatric pageantry employed by Popery, and the grovelling superstitions to which it has been made to minister, has led us to run into the contrary extreme, and to reject it altogether, with somewhat more of narrow sectarian zeal than either prudence or real consistency.

Whether unjustly or not, the Reformation is generally charged, even by those who adhere to its doctrines, with having operated most unfavourably upon the fine arts, both architecture and painting. In consequence of Protestantism having withdrawn the patronage of the church from them, those arts, it is asserted, the latter more especially, have not only lost much of their influence and authority, but have actually deteriorated—have sunk down to a lower sphere, where they can no longer put forth their energies, and exhibit themselves in their majesty and splendour to all classes of the community without distinction. Painting may now be said to employ itself merely for the opulent, and for such of the other classes as have opportunities of visiting exhibitions, which are, unfortunately, so constituted as to minister quite as much, if not more, to frivolous curiosity—to lounging gossiping about art—than to art for its own sake, and in its better spirit. By far the greater mass of the population of this country have not the means of forming acquaintance with it in any shape, excepting it be that where we behold it sunk down to disgrace and deformity, without a trace left of its intellectual character, but grovelling down to the level of Jack-Sheppardism and Co. in literature. To the lower orders of English, painting is as unknown, its powers and capacities as undreamt of by them, as by the negroes in our sugar plantations, or the colonist in the back settlements of America. Neither is this the only consequence—whether an ill or merely indifferent one in itself—resulting from the exclusion of painting from churches and other places of social worship: since thus debarred from exercising their powers on an adequate scale, both the art and its professors are compelled to abate their enthusiasm, to lower their tone and their pretensions, and, instead of abandoning themselves to nobler impulses, thereby seeking to raise others to a calmer and loftier sphere, above the vulgar region of ordinary sympathies and affections, their high calling is more or less lost sight of, the ambition that would lead to great aspirings quite benumbed. Hence that branch of the art which is somewhat incorrectly termed historical painting, it being in fact that wherein its inventive and poetical faculties are chiefly exerted, declines, and sinks in public esteem; while those branches which confine themselves to matter-of-fact reality, and demand no loftier talent than manual dexterity of execution, usurp the place of the other, till *materialism* comes to be almost our established creed in art.

Pursuing the above train of remark, we might go on to show that when shut out from religious edifices, the species of painting here alluded to finds no other congenial abode—scarcely a place of refuge. Withdrawn from the gaze of the multitude, they learn to dispense with it, or rather have now to learn that the art admits of being applied more worthily than it at present is. On this account is it that while it is rejected by the church, it equally fails to obtain patronage from other public bodies. Our civic companies and other societies afford it no admittance within their halls, except in the humble quality of portraiture, or what is not a step higher removed from it.* Under

such circumstances, little is to be expected from individual and private patronage, more especially for works of that high class on which the glory of the great Italian schools chiefly rests; because those who can afford to indulge their taste for such productions naturally prefer specimens of those schools—works of already established reputation. Besides all which, although our Protestant feelings are not shocked—whether they ought to be so, is another question—at meeting with many pictures in the galleries of our opulent collectors that are stamped most strongly and undisguisedly by the Romish creed and cultus, it does not follow that objections would not be entertained against religious subjects more consonant with our own belief. On the contrary, it is precisely because we have no reverential sympathy with them, that we do not feel at all scandalized at beholding subjects borrowed from the mythology and legends of modern as well as ancient Rome placed upon much the same footing, as mere objects of virtù; whereas it might seem to partake as much of profaneness as the reverse, were an artist commissioned to decorate a luxurious modern drawing-room with Scriptural pieces. Let them be what they might, hardly could they fail, if noticed at all, to strike as most incongruous subjects where the tone of everything else is so diametrically opposed to them, and where the frivolous gossip or the fashionable scandal of the day is retailed as conversation. The feelings—or if such be deemed the more suitable term—the prejudices that restrain us from employing painting to embellish the house of prayer and devotion with scenes drawn from holy writ, ought likewise to withhold us from making such subjects the ornaments of our dwellings, thereby depriving them of their solemnity, and rendering them familiar objects which, if not utterly indifferent, must frequently be felt to be most inopportune. So far, therefore, we are at least somewhat consistent in affording no encouragement, either public or private, to that branch of the art which the Romish church has especially patronized. Which being the case, it is not at all surprising if the talent that should be exerted upon it is turned aside into other channels; far more wonderful would it be, if artists were to devote themselves out of sheer enthusiasm to that cultivation and exercise of their energies, which would lead them to poverty, if not to absolute starvation.

Do what we may, so long as painting shall continue to be dissociated from the intercourse of public life—from both the civil and the religious institutions of the community, it is idle to expect it should ever be again re-instated in the imposing majesty it possessed when the art was intimately allied with religious creeds and popular sympathies. It may continue to appeal to the *taste* of the few, but cannot be made to engage the *feelings* of the many, although it may catch their transient attention. The consciousness of this depresses the artist, and deadens all those loftier impulses which should animate him; for he knows that were he to succeed in subjects of the class alluded to, they would be regarded as little better than happy counterfeits and semblances of bygone traditions of art—things to be criticised by *rule*, instead of being contemplated with the same spirit as that in which they were conceived.

After all, however, it may be asked on the other side, is there not little—or, more than a little, a prodigious deal—of cant about the efficacy and value of art as a means of moral instruction? Now, to speak honestly, we confess that such appears to be, to us, the case as there is a great deal of cant, of well-meant exaggeration, of over-

halls and public rooms in the New Houses of Parliament. Yet such report may be merely an *on-dit*; at all events, several years must elapse before the building is so far advanced towards completion as to admit of anything of the kind being commenced.

* Of the moral and intellectual influence of the fine arts, we once received a practical lesson that has not been thrown away upon us. It was at a public dinner of artists and amateurs, where in due course were served up sundry fair spoken speeches relative to the importance and moral value of painting and the fine arts generally, which, though they might seem germane to the occasion, we could not help thinking were somewhat superfluous and impertinent, it being likelier than not that the company present hardly required to be told that "there's nothing like leather." But now comes the real moral of our anecdote:—no sooner had the chairman vacated his seat to his "*Vice*," than one of the company being called upon to oblige the rest by the exercise of his vocal powers and gift of "harmony divine," roared forth a bawdy song, no less intolerably stupid than disgusting!

* We have heard that Cornelius the celebrated German artist is to be invited over to this country, for the purpose of painting in fresco some of the
No. 56.—VOL. V.—MAY, 1842.

strained affection, of blind partiality shutting its eyes to all sober, disagreeable truths. The example of ancient Greece is almost sure to be quoted on every occasion of the kind: yet what did art effect there? it merely softened and refined manners, without purifying morals, being in itself sensual, and often grossly so—to such a degree, in fact, that it might be supposed to have been intended to countenance human vice by examples of deified profligacy—to sanction depravity, and invest the most shocking turpitude with alluring elegance conferred upon it by a master hand. If we turn to art during its palmy state in more modern times, our scepticism as to the efficacy claimed for it is not greatly diminished, when we observe the not particularly laudable versatility of talent with which subjects the very antipodes of each other in sentiment have been treated with equal *gusto* by some of the first masters—those who have obtained credit for having been almost inspired in many of their sacred compositions. Their sympathies seem to have been so truly *Catholic*, that nothing came amiss to their pencils. A Venus or a Virgin, a Magdalen or a Messalina, the seven sacraments or a lewd bacchanalian revel, have been treated by them with apparently the very same relish and sincerity of feeling. He who worked one day for the church and the devout, attempting themes celestial, glorified saints, and the supernal paradise itself with its angelic hosts, could, the next, work, nothing loth, for the carnal-minded and profane, and depict, with far more of nature than decorum, the libidinous amours of the heathen Olympians. The fact itself is indisputable; but then have we not acted unadvisedly, in calling attention to what seems fatal to our own side of the argument—that is, supposing our real intention be to advocate the introduction of painting into our own churches?

Most certainly we should have kept such awkward and disagreeable events, by urging only what would show it to be of paramount and all truth out of sight, did we either only seek to recommend painting at unimpeachable excellence, or else imagine what we have thus frankly stated to be in itself a fatal and insurmountable objection. Now, we do not hold, as many others appear to do, that there is any abstract unconditional merit either in painting, poetry, or any other of the fine arts, let the talent—or, if it pleases better, the genius—exerted upon them be how excellent soever in itself. It is not the *power* actually manifested, but the *aim* to which they are directed, that renders literature and art a blessing or a curse and pestilence to society, accordingly as they bring with them “airs from heaven, or blasts from hell.” We neither claim nor recognise for them any prerogative divine; so very far from it, that we abhor the cant which endeavours to do both. We do not see, therefore, how the laudable use of art can be made to justify the abuse of it, or how its perversion can fairly be employed as an argument against the application of it to a meritorious purpose. Neither are we of opinion that Protestantism is so utterly irreconcilable with painting, as to be unable to avail itself of it without in some degree compromising its principles and character. On the contrary, it appears to us that it would in one respect be more favourable to art than even Roman Catholicism, inasmuch as it would confine it to its legitimate sphere—that of illustrating events recorded in Scripture; and would prohibit all those offensive extravagances which, in Catholic countries, the pencil has been allowed to indulge in, such as representations of the Deity himself, and spiritual and invisible existences on the one hand, and insipid groups of the Virgin and favourite patron saints, together with traditionary legends and similar fancies, on the other. Nothing can be more shockingly irreverent, yet absurdly puerile withal, than the anthropomorphism which presumes to image forth the First Person of the Trinity under a figure and countenance bearing more than an accidental resemblance to the personification of the supreme Jove, the father of the gods, by the ancient sculptors. The Protestant church, again, recognizes no female divinities, nor any of those other divine personages to whom the polytheism of modern Rome has erected altars; its artists would, therefore, be in no danger whatever of following too closely in the footsteps of Catholic painters. Whether or not they would, in consequence, be prohibited from approaching subjects which, partaking as they do of the fancies and fictions of a semi-paganism, afford a freer scope for the imagination

and for the pencil than the mere records of Holy Writ, so that it would be disadvantageously fettered down to literal truths, is what we leave others to decide; only remarking, that if fiction be essential to the poetry of art, the Romish church possesses that element of poetry and artistical inspiration more abundantly than its followers will care to allow.

Let the pencil be strictly confined to such subjects as are supplied by the historic records of the sacred writings, nor presume to reveal to mortal eye the visions of a world to come—mysteries beyond the faculties of finite beings to conceive—even to adumbrate in the most inspired flights of poetry, much less to shape and body forth tangibly to the sense of vision. We strongly protest against such awful impieties of art as are some “Last Judgments,” even though as works of the pencil they may seem almost superhuman achievements. Considered calmly yet seriously, what are the most miraculous productions of the kind, other than splendid absurdities, gorgeous incongruities, sublime puerilities; in a word, the extravagance and the impotence of art? Let their æsthetic worth be ever so great, representations of that kind must in themselves be mere *conceits*, because that is attempted to be visibly embodied which in itself utterly surpasses conception; accordingly, except as performances of art, they are not superior to the vulgar, rude, bugbear pictures of purgatory so common in Roman Catholic countries. But if the reader cares to be further edified on this topic, let him peruse George Forster’s criticism on Rubens’ celebrated Last Judgment at Dusseldorf.

There is no danger of our adopting such solemn extravagancies of the pencil; but there most unquestionably is not only a strong prejudice against countenancing painting in our churches, but it seems to be assumed that, even were we disposed to do so, the spirit of Protestantism itself is so uncongenial to that warmth of rapturous fancy, without which the artist can neither worthily conceive nor finish up his conceptions of subjects which ought to awaken corresponding emotions of reverence in the spectator, that all patronage and encouragement would prove totally unavailing—would be attended with no other effect than that of furnishing employment to painters and colour-manufacturers. It is far more easy to make similar assertions than to disprove them, for the simple reason that no opportunity has been afforded of putting them to the test, by any practical effort to demonstrate their futility by proving the contrary. *Fac periculum* would, therefore, be our advice. Yet when Reynolds and many of the Academicians of that day offered to the Dean and Chapter to decorate St. Paul’s with paintings gratuitously, the scheme was frustrated by the opposition of the then Bishop of London, who refused his consent on the grounds that it would be introducing Popery into the metropolitan cathedral, or rather, we presume, out of the apprehension of its being so construed by others. It is not every Protestant clergyman, however, who entertains the same scruples, for among Dr. Vicesimus Knox’s Essays there is one which warmly recommends the adornment of churches with paintings, as being at all events harmless and unobjectionable, and likely to be sometimes efficaciously impressive. If, indeed, it can be shown that, so far from tending to promote devotional feeling in any degree, pictures in churches would be calculated to produce a contrary effect, the repugnance to them would be rational and laudable. But to reject merely because the Romish church adopts them, seems to us to savour quite as much of indiscretion as of sound policy; since by laying too great stress upon what is utterly matter of indifference as far as concerns the principles of the two churches, we elevate it into a sort of virtual distinction, if which were repealed, there would be danger of Protestantism and Popery being confounded together. Surely the irreconcilability of their respective doctrines and tenets might suffice to remove all apprehensions of such nature; moreover an argument on the other side might with equal propriety be founded in favour of painting, inasmuch as the introduction of it would serve as an additional distinction between the Established church and all the sects who dissent from it. Almost might it be imagined that painting was the very badge and livery of Rome—the mark of the Beast—from whom it behoves us to keep aloof; whereas in truth it is neither essential to Popery, nor at variance with Protestantism. Were St. Paul’s

adorned with Scriptural subjects filling up those compartments which its great architect contemplated as being one day so occupied, it would not on that account partake one whit more of Romanism than its dome actually does at present, or than its Corinthian columns do of Pagan mythology and the religion of the Greeks. Nay, both those architectural features of the edifice and the style generally might, on such grounds, be considered equally exceptionable, as reminding us too forcibly of the Roman Catholic temples of Italy; while it at the same time becomes doubtful whether there be not some impropriety—some abatement of the wholesome horror of Popery—in permitting ourselves to revert—to relapse into our ancient ecclesiastical style, which flourished here when this country submitted to the spiritual jurisdiction of the Vatican. Mr. Welby Pugin—no mean authority, perhaps, on such a point—considers Gothic architecture and Roman Catholicism to be so intimately connected together, that the former cannot possibly thrive—indeed, hardly maintain itself at all—apart from the protection and influence of the other; yet, so far from entertaining any disquieting scruples against it, we have of late professed ourselves practical admirers of our own indigenous Roman Catholic style of building for new churches and chapels, endeavouring to copy its models as closely as circumstances would permit. Were any *anti-Gothic* critic or dilettante so disposed, he might make use of this last-mentioned fact, and earnestly deprecate such return to the “barbarous monkish style” of our ancestors, not merely as a backsliding in taste alone, but as betraying a dangerous leaning towards the church whose erroneous doctrines we have repudiated; a tendency which it behoves us particularly to guard against just now, when Popery we are assured is gaining ground in this country, and certainly does seem to be putting forth its strength—its attractions and seductions, in the costly edifices it is erecting in various districts of England. For ourselves, we look upon its efforts of this kind without apprehension, considering the alarm attempted to be excited against them to be a mere bugbear, little better than the watchword of a party.

No; we certainly do not wish to approach at all towards Romanism, neither do we consider that throwing open our churches for the admission of paintings by Protestant artists would be an approach to it, any more than walking from Westminster to Highgate can be called approximating to the North Pole. Still, it does not follow that, independently of a seeming tendency to Popery, there may not be objections against paintings, on other grounds—as beneath the dignity of a spiritual worship; as withdrawing attention from the word to visible objects; as adventitious aids which true devotion does not require. Certain, however, it is that, exclusively spiritual as may be the religion they profess, the mass of mankind are unable to abstract themselves entirely from external impressions, but feel an increased degree of awe and devoutness in proportion as religion is allowed to display external majesty and solemnity; whereas the bareness which characterizes most of our churches, does not look altogether so much like simplicity as like penurioseness, begrudging to the house of God that degree of becoming adornment which we bestow upon our own homes.* Besides, if objected to upon principle, all decoration of the kind ought to be consistently excluded; which certainly is not the case, because painting is frequently admitted for altar-pieces—nay, there are instances of the works of Catholic painters being so introduced, without any exception being taken to them as opening the door to Popery. Nor have we only pictures of that kind, but painted windows, exhibiting the livery of Popery in figures of legendary saints, or else displaying heraldic emblazonments—the pride of the creature, in temples raised to the Creator. Nay, we will not be quite sure that, if paintings of Scriptural subjects are to be prohibited, we ought not to be scandalized at beholding Westminster Abbey and St. Paul's each

converted into a sort of lay Pantheon, and filled with monuments to men illustrious not as exemplars of Christian virtue and piety—as faithful servants and champions of the church—but for secular services performed to the state and the community. Dramatists, actors, artists, poets, musicians, *hoc genus omne*, together with a host of naval and military characters, sufficient to form a United Service Club,—such are the personages who are admitted to posthumous honours in our religious edifices, after undergoing a sort of Protestant canonization from the public. While both the author of the *Beggars' Opera* and the author of the steam engine have obtained such distinction within Westminster Abbey, without its being considered any profanation to the sanctity of the place, in vain do we look there for any testimonial of national respect to talent and piety, in the persons of such individuals as Milton, Cowper, and Hannah More.

As regards the possibility, however, of enlisting the arts in the service of religious worship, we are of opinion that were the inclination to do so to be manifested on the part of the church itself, many private individuals would contribute towards such purpose, and as the taste so fostered spread itself, others would be stimulated to emulate their example; whereas at present all feeling of the kind is totally discouraged among Protestants, and although a man may erect a church or chapel at his own cost, he cannot contribute towards the embellishment of one by a painting or other decoration, so that by various similar donations and acts of munificence, a religious edifice might eventually be completed in all its embellishments. In fact, we seem to have now no idea of gradually perfecting a structure of the kind in all its parts, but what cannot be accomplished at first out of the original funds is never afterwards attempted to be effected at all; one serious ill consequence of which is that the designs for our modern churches are never made with reference to any after-growth of ornament, or any subsequent finishing up of what has been in the first instance only provisionally schemed. Hence the designs are cramped and stunted in their very conception, and are impressed with a littleness and meanness which, even were it applied, no after study or polishing up can obliterate. Such was not the system by which those glorious fabrics of Catholic times were achieved. Unlike the vulgarly spruce mushroom churches and chapels of the present day, they were generally the matured growth of generations, if not of centuries; and embellishment continued to be added as the means for doing so were afforded, until they became what we now behold them. But, as we have already hinted, almost any building that will afford sufficient accommodation for a congregation is considered good enough for a church:† nothing farther is expected to be supplied, after it is once erected—no farther thought and attention, beyond that of keeping it in necessary repair, bestowed upon it.

Almost would it seem that Protestantism made a merit of discouraging architecture, as well as not encouraging painting; for undeniable it is that by far the greater proportion of the numerous churches erected of late years are anything but satisfactory in design, in many cases totally the reverse, and that not entirely because the funds have been insufficient, but on account of the excessive littleness and paltriness that stamp every part of the buildings. The primary consideration seems to have been to provide at all events one or two routine features, whether any other part can be made to accord with them or not. If the style is to come under the denomination of Grecian or Roman, a common-place erection of four or more columns, concocted according to the usual recipe for making a portico,‡ and which the

* Nay, while the average cost of our recently built churches does not amount to more than 3 or £4000, no less a sum than *seventy thousand* has been expended on stables at Windsor Castle, besides we know not how much more on other stables for royalty at the Ascot race-course; for which last there certainly cannot be the plea of necessity—so far from it, that we think a female sovereign and her court might very well be excused from countenancing horse-racing in any shape whatever; downright gambling, and nothing else, being at the bottom of it.

† Now and then, indeed, an exception occurs; and as an instance, we may mention the new church at Lee, near Blackheath, which, besides having all the windows filled with stained glass, is consistently finished up throughout, and the interior has the singular advantage of being unencumbered by side galleries. The church now erecting at Streatham by Mr. Wild promises also to be one of superior architectural merit, and of very unusual design, the style partaking of the Italian *Vergothisch* or Lombardic, with some intermixture of polychromic embellishment. A good deal of coloured decoration will likewise, as we have been informed, be introduced in the interior, and, among the rest, that of ornamental terracotta tiles both for the pavement and for parts of the walls.

‡ Our modern porticos are at the best seldom more than *monoprostyles*, for the explanation of which and several similar terms, and also for a variety of interesting remarks on the subject generally, we refer the reader to the article *Portico* in the *Penny Cyclopaedia*, and in the *Journal*, vol. iii, p. 389.

junior clerk in his office can draw out as well, perhaps better, than the architect himself, is stuck up in front; no matter whether the rest can be made to correspond in any degree with the style attempted, or indeed whether it can be afforded to let the entablature be of a piece with the columns. Or if Gothic be preferred, we are generally treated with naked and mullionless pointed windows, in what professes to be the earliest mode of that style, but which in fact is rendered utterly dissimilar in character—as pert as it is paltry. Even where some parts are really good in themselves, there are almost invariably some glaring blemishes to neutralize their effect, and to render the ensemble preposterous and offensive. Vain is it to look for attention to unity of character, and consistency of expression throughout, where there has evidently been no feeling brought to the task, and where the architect himself has not brought forward a single idea followed out *con amore*; but appears to have been utterly indifferent to aught beyond the mere business and trading part of his occupation, as if his title were to be taken in its literal import, and “Architect” meant no more than chief or master builder contracting for the job.

Were plainness and simplicity identical qualities, or did the absence of decoration constitute soberness, or were chilling frigidity the same as solemnity, then might our present church architecture fairly challenge that of any other age or nation for its excellence in regard to those merits. Unfortunately for it, such is not the case: in vain do we look for either simplicity or soberness: while as for solemnity or aught approaching it, that is entirely out of the question, although it would seem to be the quality of paramount and indispensable importance. “Among all the new churches I have seen,” says Candidus, fasciculus 13 of the second series of his “Note-book,” “I have certainly not beheld one possessing internally anything like solemnity in its general effect; on the contrary, differ how much they may as to all other circumstances, they agree as far as the absence of that quality goes. Some are dismal and mean enough; others, if not particularly tasteful, smart enough, just the very places for a fashionable congregation, whom the architect generally takes care to arrange so that they shall make as goodly a show as the audience of a theatre, and be able to reconnoitre each other without obstruction. In fact there is very much more of the playhouse than of the house of prayer in such buildings—nothing calculated to inspire feelings of reverence. Neither does it make much difference what style be employed, since the interior of our modern Gothic churches have no greater air of impressive solemnity than have those in any other style.”

Were we ever so much disposed to contradict such opinion, we cannot attempt it, for among all the newly-erected churches we have visited, we do not recollect one that can be quoted as an exception; on the contrary, we have been disagreeably struck by several that strongly corroborate the observations we have copied. Much of the want of solemnity above complained of arises from the cold and raw appearance of the interior generally, owing both to the quantity of light which is insisted upon as indispensable, and the almost total absence

* A recent article on new churches in the British Critic contains some exceedingly judicious architectural observations relative to that spurious early Gothic, with lancet windows, or rather mere holes in the wall, which is now so greatly in vogue with the cheap church-builders of the day. In a previous paper on the same subject in that periodical, there occurs likewise a suggestion which, should it ever be acted upon, would tend materially to improve the architectural character of our Protestant churches, namely, that there should be not a mere shallow and confined lobby, as at present, but a spacious vestibule or pronaos between the entrance from the street and the body of the church itself. “There should be something to create the idea of retirement, and distance from the public thoroughfare, like the ante-chapels of our colleges.” The circular part of the Temple church is mentioned as furnishing a hint for the purpose; and a very recent application of such sort of pronaos may be found in the elegant chapel of St. Mark’s, North Audley-street, which, if merely on account of that circumstance in its plan, deserves especial notice among contemporary structures of the same class in the metropolis. A vestibule of this kind, it is further observed, “might be always open during the day, as Guildhall is, without inconvenience; and it might be the place for sepulchral monuments, and for other memorials and inscriptions of a not entirely secular character.” We will add, it might be the place too for paintings of Scriptural subjects; but then, unfortunately, we have no notion in this country of monuments and pictures being exposed to the view of those who cannot afford to pay for seeing them as sights; but they must be as rigorously excluded from the gaze of the profane and vulgar, as if there was danger of the taste of the lower classes being degraded and their morals corrupted by contemplating such works of art.

of colour, except it be occasionally in columns and a few other parts, in which, so far from tending to produce richness, it chiefly occasions spottiness, and a disagreeable littleness of character. Now whatever objection may exist to painting in the form of pictures, hardly can there be any to it as mere colouring, for the purpose both of giving somewhat of richness and finish to the building, and of sobering and toning down that offensive glare which now prevails unmitigated throughout.* It further appears to us, that beautiful and expressive features as are the windows of our ancient Gothic edifices, filled with bold mullions, rich tracery, reticulated panes, and perhaps coloured glass, shedding a “dim religious light,” a mellowing hue, and flickering gleams and shadows around, windows of similar outline lose all their beauty when reduced to mere vacant apertures, as is the case in most of our modern Gothic church specimens, and where such apertures are besides no further apart from each other than they would be if the light were partially obstructed and subdued by mullions and tracery. In the other or Grecian style, windows are not a whit better, in fact operate as a drawback upon the style itself, both internally and externally; which defect is all the less excusable, because, not being characteristic and congenial features belonging to the style itself, nothing would be easier than to get rid of side windows altogether, there being so many various modes of admitting light through the roof and ceiling, any one of which might be adopted, according as it would best suit the particular design: and if light is, as has been quaintly observed, “God’s eldest daughter,” there surely can be no impropriety in allowing it to flow down into a place of religious worship immediately from above. The new church of La Madeleine at Paris is lighted entirely after this manner; and although we cannot refer to a single structure of the same kind in this country, where that mode of lighting it has been adopted, we have several and very well known instances in other buildings of its practical application and success. The hall of the Elgin marbles at the British Museum, most of the offices at the Bank of England, the picture-rooms at the National Gallery, the Pantheon Bazaar, the great room at the Polytechnic Institute, and, indeed, most large apartments intended for public meetings, are now so constructed and lighted, although so very differently that hardly any two examples will be found precisely alike. Putting Gothic architecture out of the question—for there, except by perforating the tracery of a vaulted roof, the nearest approach to this mode of lighting from above would be by clerestory windows forming a lantern over the body of the church—putting, we say, that out of the question, there is nothing which is so favourable to architectural display and picturesque effect in the interior of a building as the streaming in of light from above diffusing itself beautifully in a single volume, instead of forming as many distinct spots as there are windows. It is precisely in the magical effect thus produced that the charm of the Pantheon at Rome, as an architectural picture, consists; and yet strange to say, with all their professed admiration of that building, none of our architects have adopted for any of our churches the idea it so plainly holds out.

In fact, it is only by getting rid of side windows, that adequate spaces for paintings on the walls could be obtained in our English churches, should the time ever arrive when, relieved from our bugbear apprehensions of Popery, we should deem it rather a mark of respect than a profanation to array our temples with storied representations of

* Be the objections made against pictures in churches, as partaking too much of Popery, well or ill founded, they certainly need not prevent our adopting a nobler, or rather a less mean and impoverished style for the edifices themselves, very few of which, among those lately erected, are at all decently adorned, even as Protestant places of worship; because there is certainly no danger whatever of their being made to resemble those adapted to the Romish service. At present almost anything like architectural effect is entirely out of the question; and the galleries are frequently suffered to occasion if not exactly a theatrical, a very playhouse-like look. For the management of those somewhat unmanageable and refractory parts, and also for the general disposition and mode of fitting up the interior, we would refer to a structure which, if not Protestant, is incontestibly not a Catholic one, namely, the new synagogue in Great St. Helen’s, Bishopgate-street; which, without being at all over-decorated, in some respects rather less so than we could wish, is a handsome and elegant piece of internal architecture, and might be studied with some advantage by our modern church-builders, unless indeed, our delicate scruples should reject anything from such a source, as being likely to lead us to Judaism.

Scriptural subjects—innocent as embellishments—possibly more or less efficacious as impressive lessons, and aids to devotional feeling. At present there is hardly a church, except St. Paul's, calculated for the reception of wall-paintings, yet of such decoration even that, we find, has been deprived, through the over-scrupulousness of one who could enforce his *veto* against it; and perhaps, were it not that they are utterly lost in obscurity, the same worthy prelate would have condemned Sir James Thornhill's paintings in the cupola to be expunged by whitewash. The exterior itself of the cathedral might at the present day be objected to by some, as presenting in its noble domes, its statues, and other ornaments, more of a Papistical physiognomy than is becoming in a Protestant church of any kind.

There is, we suspect, no small degree of superstition, or else regard to the superstitious fancies of others, in that excessive and over-zealous avoidance of things perfectly indifferent in themselves, merely because they have been used—perhaps greatly abused—by the followers of a different creed. But is not this apparent virtue a fault, and that by no means a light one, partaking as it does of that haughty and uncharitable spleen, which our Lord himself omitted no opportunity of reproving in the Pharisees, against whom, as has been remarked by a certain writer, all meek and humble as he was, he was continually directing the severest sarcasms and the most pointed irony.

That we may allay the fears and scruples of those who in their just aversion to Popery look upon painting and sculpture in churches as part and parcel of it—as among its enticements and defilements—we will now listen to Dr. Grüneisen, whom, to say the truth, we have kept in the background so long, that our readers may have begun to suppose we did not intend to admit him further than the threshold of our article. Now, as is evident from the title he has given it, the scope of the Doctor's dissertation—which, we may observe, appeared on the occasion of the Reformation festival at Leipzig, 1839—is to show that the principles of the Reformation do not demand the renunciation of the fine arts, or their expulsion from the service of the church; and that it is a mere vulgar prejudice to imagine that the reformers themselves either desired or contemplated any such result, but merely sought to abolish those idolatrous pictures and statues to which the Romanists ascribed supernatural efficacy or particular sacredness, together with relics—always doubtful, and for the greater part, merely fictitious. The indiscriminate *Bilderstürmerci* and spoliation of works of art in churches and religious houses proceeded entirely from the lawless fanaticism of the people, who, in all sudden changes, whether political or religious, think they cannot better display their sincerity in favour of one cause, than by blindly attacking and wreaking their vengeance upon whatever is considered by them identified with that of their opponents. So far, however, were the heads of the Reformation from sanctioning or any way countenancing this zealot Vandalism—albeit some Protestants of the present day would perhaps show themselves less scrupulous and less moderate—that they exerted their authority and influence to arrest the mischievous havoc, as far as was then possible, even at the risk of offending their own intemperate partisans. To look upon them, therefore, as the instigators and abettors is a calumnious error: with far more truth and reason may the Romish church be charged with directly sanctioning those idolatrous superstitions and practices among its followers which it affects to disown for itself; inasmuch as it has tacitly connived at and profited by them, without lifting up its voice against such enormities.

Zwinglius expressly says, "*statuas, imagines, et simulacra, nemo tam stolidus est, qui putet abolendas esse, ubi nullus eis cultus exhibetur*"; and although he remonstrates against the papistical use or abuse of such representations, "*alioquin,*" he adds, "*nemo magis miratur picturas, statuas, et imagines quam nos.*" Very few will attribute much laxity, or indeed any want of rigour to Calvin, and yet we find this stern reformer speaking with a liberality in favour of art that is little less than startling: "*neque tamen eâ superstitione teneat, ut nullas prorsus imagines ferendas censeam. Sed quia sculptura et pictura dona sunt Dei, purum et legitimum utriusque usum requiro, ne quæ Dominus in suam gloriam et bonum nostrum nobis contulit, ea*

non tantum pollutantur præpostero abusu, sed in nostram quoque perniciem convertantur." Here he openly vindicates the employment of both painting and sculpture in the service of the church, and for the adornment of its temples, calling them gifts from God, and making use of the very strong and remarkable expression, "*neque eâ superstitione teneat,*" which may be interpreted "I have not such a blind and superstitious horror of the superstitions of popery as to imagine that all pictures ought to be interdicted." Indeed, he elsewhere recommends the introduction of historical subjects from scripture as silent admonitions, and incentives to godliness. In short, we believe that the Royal Academicians would have succeeded far better with John Calvin than they did with the Bishop of London, who, when they applied to him, certainly evinced some of that *superstition* which the celebrated reformer disowned. Yet, as we are not Calvinists, and therefore his authority may have comparatively little weight, let us turn to Luther, whose opinion ought certainly to stand for something; and, undoubtedly to the surprise of many, we find him taunting the *Bilderstürmers* or iconoclasts, and destroyers of church pictures and images, with tolerating similar representations in the wood-cuts of their German bibles. "I humbly crave, therefore," he adds, "that they would allow the same license to us, and permit us to adorn our walls in like manner as they do their books, with images forcibly calling to mind, or else serving to explain, what is recorded in Holy Writ; because I see not how they can be more hurtful when delineated upon a wall, than on the page of a book. Would to God I might persuade our great and wealthy ones to have the entire bible painted both outside and withinside their houses; that would be truly a Christian work." Without exactly assenting to this last opinion, which appears to us of very questionable propriety, we may be satisfied with the direct and explicit testimony given in favour of painting and sculpture as suitable adornments for churches, by those who, as Anti-romanists, are generally supposed to have viewed them with abhorrence, and to have laboured to suppress them.

The other fallacy or error here combated is the prevalent idea that, independently of the change in religious worship, the Reformation has proved of evil influence upon art generally, there being, in the very constitution of Protestantism, what checks and prevents art from coming to full maturity, although it may not actually blight it in the bud. We grant that no second Raphael or Michel Agnolo has arisen as a luminary of Protestant art, that painting has upon the whole declined since the period immediately preceding the Reformation; and had such declension been confined to those countries which embraced the reformed faith, the argument sought so to be established might be received as a valid one; whereas the case stands altogether differently, since it is precisely in Catholic and papal Italy itself that the fine arts, and painting more especially, sunk almost to degradation—to mere mechanical and tasteless routine—to insipidity and almost to imbecility, during a considerable portion of the two last centuries, although it would seem that if Catholicism and Protestantism had any share in the matter, it ought to have received a fresh impetus in Italy, from the roused spirit of rivalry, and the desire of opposing the majestic array of Catholic worship in all its splendour, to the tasteless and cheerless poverty of that of the reformed church. Allowing, therefore, that it was their religious faith and the æsthetic influence of their creed which, animating the great Catholic artists of other days, and enabled them to achieve works that seem almost to have been inspired, we must conclude that the prompting, devotional spirit of their creed has long since passed away, and that Romanism itself is now little more than nominal, compared with what it formerly was. Either the cause alleged was not the real one—or at best, but one concurring with many others, or it has now ceased, since it most evidently is no longer in operation. On the other hand, Romanism favours a good deal that is most anti-æsthetic, and attaches a high value to many things that art would repudiate, either as absolute deformities, or as vain baubles and gewgaws. What shall we say of that pious taste for bijouterie which the Romanists practically attribute to their saints?—of diamond necklaces and other trinkets, childishly dedicated to the Madonna? "The pomp exhibited in architecture

and painting," says the author of 'Records of a Route, &c.' "is intelligible enough; not so that which consists in treasures hoarded up in cases, which do not contribute even to make any show in the way of the furniture of a church, as is the case with magnificent candelabra and other utensils. Treasures of that kind are fitter for a goldsmith's or jeweller's shop, or for the toilette of a fine lady, than as offerings to a saint." In regard to relics—but no! there is no occasion for our making any comment upon them, they being of themselves calculated to do eminent disservice now to the cause of Romanism, by exciting contempt and ridicule against it.

The second work whose title is prefixed to our article is by a minister of the reformed church in Switzerland, but who nevertheless advocates some relaxation of that austerity which has hitherto characterized the religious community to which he belongs, and given a repulsive coldness to social worship, the reverse of alluring. The ascetic renunciation, he observes, of all that partakes of æsthetic feeling—of all that ministers to refined, intellectualized enjoyment—demands a degree of spiritual perfection that falls to the lot of few; while to the many, it only renders what ought to be devotion a frigid and formal penance. And indeed the exaggerated rant of the conventicle seems to be almost necessarily resorted to, by way of equivalent, for producing that excitement which the religious pageants of the Romish church supply. Both extremes have one aim in common, and both partake of acting for the sake of effect, though the means resorted to for producing it appear so contradictory.

Contenting himself with cautioning against abuses, the anonymous writer last referred to expressly recommends that the church should be allowed to enlist the fine arts in its service. Neither is he by any means singular in his views, for both the Lutheran and the Calvinistic churches in Germany have of late begun to relax their former strictness in that respect; and that reaction seems now to be taking place for which the public were prepared by the official announcement of the Prussian minister Von Schuckmann, in 1814, wherein it was signified that it behoved the church "to give greater solemnity to the form of religious worship, inasmuch as that at present adhered to does not at all address itself to the feelings, nor is sufficiently impressive."

How far the same remark applies to the service of the church of England, we pretend not to judge; yet certain it is that a great majority of our churches, including those of some of the wealthiest parishes, are barely decent, and no more, in their fitting up—not squalid, indeed, but stamped by such begrudging penuriousness, as to betoken anything but excess of zeal. Nor can we attribute this either to the rigid ascetic notions of the age, or the poverty of the country; for the age is liberally indulgent enough, and of wealth there is also enough, but the spirit of the age is selfishness—cold, calculating selfishness. At the same time, it must be allowed that the church itself has rather repelled than invited private munificence to contribute towards the adornment of its temples and its service. However, we will not quarrel with such a state of things, even for the sake of upholding the cause of art, towards which our affections yearn. Yet, while we make such concession, we expect some also in return, and, therefore, claim that Protestantism should not be made to bear the odium of condemning us to shut the doors of our churches against works of art. If we either cannot afford, or do not think it worth while to obtain them, we are perfectly satisfied with either of those honest and very intelligible reasons: it is our pockets, not our Protestantism, that suggest our sensitive scruples. As to scruples of any other sort, they are all make-believe. There is not the slightest danger whatever of pictures tempting us to relapse into Popery, or gaining us over to its monkish charlatanism, its polytheism, and its miracle-mongers. We are just as likely to become converts to a belief in witchcraft, as to Romish idolatry. The taste of the age in osteology is for bones of megatheriums, not for those of Saints. Why then so much affected alarm? Between the doctrines of Romanism and those of Protestantism the gulf is so wide that art can never bridge it over; and, of the two, Romanism is infinitely more in danger than Protestantism, for the simple reason that is stated by the Italians themselves, in a proverb that cuts their own creed most keenly—"Con L'EVANGELIO si

diventa ERETICO!" Yes, the Gospel is, after all, the great and never-failing source of heresy—of that most awful heresy which alienates men from the craftily-devised chimeras, and the simulated Christianity of Rome.

ON GRECIAN ARCHITECTURE—ITS BEAUTIES, AND THE DANGER ATTENDING THE IMITATION OF THE STYLE IN MODERN TIMES.

To point out in what consist the qualities of beauty, and to make one kind of definition universally applicable, is an all but impossible matter in any case, and is especially difficult in all that relates to architecture. By Mr. Alison it has been ably argued "that in every subject that form, whether angular or curvilinear, which is most expressive of these qualities (*viz.* fineness, delicacy, or ease,) is the most beautiful form." We find little to oppose in that part of his essay which treats of colours and sounds; but on the source of the emotion in forms, and more especially in architecture, he fails. His fundamental principle is that "matter is not beautiful in itself, but derives its beauty from the expression of mind," (*Essay on the Nature and Principles of Taste*) and he instances the triumphal arch, and the temple in its primitive state, as beautiful objects, so considered, only from the perceptions of grandeur and solemnity, which they are calculated to awaken. But surely he too hastily assumes them to be beautiful, for few modern architects can see in the triumphal arch great beauty of form; and we might adduce many examples of temples, by which the emotion would not be excited, solely from their wanting those decorative features essential to its production. Mr. Alison proves, which it was scarcely required to do, that certain feelings are excited by the sight of the triumphal arch, of the undecorated temple, of the hearse, and of the engines of war; but we cannot but hold, that he errs in considering those to be emotions of beauty, for we most carefully discriminate between THE BEAUTIFUL, and what is merely the sumptuous, the reverential, the solemn, or the terrible, each of which may powerfully influence the mind, without at the same time being any proof that beauty exists, or can be perceived, in the object. An edifice may possess no one feature which an artist would call beautiful, and yet produce the very feelings of which Mr. Alison speaks. The uneducated, in standing before a large and costly edifice, may be heard to express extravagant admiration, but it is alike with them whether the design be excellent or not; they lavish the terms "grand" "imposing" upon structures possessing no one merit, because they excite in them wonder, mistaken for an emotion of beauty.—Another current opinion, which is at war with true principles of taste, is, that any building of stone is better than one of brick, whatever the design. If it be true, that the ordinary forms of the vegetable world possess as great beauty as the costly exotics of the conservatory;—if it was from the oak leaf, from the parsley, and the cabbage, that Gothic architects most loved to mould the graceful foliage of their capitals and bosses;—we ought from them to learn the true value of what happens to be common, and easy of attainment. Of what may be done in brick and stone, whether in the Gothic or the Italian style, the earlier and later portions of Hampton Court palace bear sufficient witness. The evidence of durability is as high in favour of brick as of stone.—But, whether we entirely concur in the opinions of Mr. Alison, or not, it must be granted, that much of our admiration of Grecian architecture must be ascribed to associations connected with the days of Phidias and Pericles, of the splendour which shone round all the arts, where, "on the Egean shore," stood the temples of Minerva and Theseus, and where poetry, philosophy, and the arts, combined to render "the violet queen" the centre of an ever-spreading halo, undimmed through all succeeding time. Who, that loves art, poetry, philosophy, liberty, does not feel his soul expanded and elevated at the name of Athens? what artist, at the sight of Grecian architecture, does not think of the mind that conceived, and the people

that appreciated? These are associations even more potent than any—as Mr. Alison might say—of lines and angles with strength and utility, and of curves and enrichments with elegance and grace.

In the moving and breathing figures of the procession in the Parthenon, and in the rich adornments of the Choragic monument, we are reminded of the "earth-born" people, who hurled back the invaders from the fields of Marathon and Plataeæ, and who hailed the works of Æschylus and Sophocles victorious in the theatre. Not that the intrinsic beauties of Grecian architecture are non-existent or unworthy of notice, but rather, that great as they are, they are subdued by the larger influence of intellectual association. The native beauty is beheld, in the perfect adaptation to the two ends of elegance and strength, so that the proportion, which exhibits the greatest degree of elegance, is precisely that which also resulted from the arrangement most conducive to the stability of the work. By placing the columns at short intervals, an intricate and shadowy effect was produced, at the same time that the stones of the architrave were just sufficient to support the weight of the frieze and cornice above. Further to lessen the bearing of these stones, the upper part of the column was extended, and became the capital. To improve the outline of the mass, and to throw off the water, the sides of the roof were inclined from the centre, and were formed in parallel lines down to the projecting cornice.

The theory to which we have adverted was first broached by Lebrun (*Théorie de l'Architecture Grecque et Romaine*), and has been proved by Mr. Gwilt to be by no means fanciful. In five examples of celebrated edifices, "the superficies of the columns, cut through their axes vertically by a plane parallel to the front of the building, are compared with the area of the entablature and pediment of each respectively. The weights of each being as the cubes of the square roots of the areas, these areas will equally represent the supports and weights in either of the terms.

In the Parthenon, the supports are to the weights as 1546 : 1843 or 1 : 1.19

But if the steps be reckoned, the ratio will be as 2183 : 1843 or 1 : 0.84

In the Doric Portico, the supports are to the weights as 4070 : 3990 or 1 : 0.98

In the Pseudo-dipteral temple at Paestum, the supports are to the weights as 1090 : 1108 or 1 : 1.01

In the temple of Erectheus, as 2640 : 2800 or 1 : 1.07

In the Pantheon at Rome, as 1566 : 1723 or 1 : 1.10."

(*Gwilt's Chambers' Civil Architecture, note, page 160.*)

Thus we see the impropriety of our monumental columns, which, designed for a proportionate weight of entablature, sustain nothing but a vase or a statue in most sweet communion with larks and crows; which have not even a decorated shaft, to render less striking in each, its resemblance in form, and its contradiction in end, to a column from a Roman portico. The Roman triumphal columns were not fac-similes from one temple or from another; they were not even of any particular order, and their shafts were made the means of exhibiting to posterity a history of the events they were erected to commemorate. Amid the beautiful decorations of the Trajan and Antonine pillars, we forget the impropriety of an isolated column, and look upon them as relics, handing down to us, through the stream of time, the most vivid picture of Roman greatness.

Deeply impressed as we are with the love of Athenian architecture, for its intrinsic beauties, and for the charms with which it is surrounded by association; removed from a land where sunset gilds "with one unclouded blaze of living light," "Egina's rock and Idra's isle;" rather using a portico to shelter from the elements, than to retire from the heat of the sun; it is impossible, that our attenuated copies of the fronts of Grecian temples, can strike us with other feelings than those of disappointment and regret. We have no peristyles hung with garlands and crowded with admiring votaries; our imitation is all but limited to an entrance portico, attached to the middle of a building, wholly different in character, and with which it ought to have no

connexion whatever. Our buildings stand in crowded streets, and are splashed with their mud, instead of crowning the "marbled steep" of a promontory, or the summit of an Acropolis. Stories of sashed windows riddle the front, and pots and pipes of every imaginable contortion rise from the roof. No sculpture decorates the metopes or the pediment; no colours glitter in the sun. The wall at the back of the columns seldom recedes, as in the temple of Theseus, and in that on the Ilyssus, neither are there internal columns to produce depth or intricacy. The National Gallery is one of the few buildings of modern times in which these points are attended to, and it does not, therefore, deserve all the censure it has received. In the Royal Institution at Manchester, Mr. Barry has not omitted these all-important features. The greatest fault of the National Gallery is in not placing its portico upon a bold flight of steps, but, instead, upon a podium, a thing never done by the Greeks, and never by the Romans in the main front. We see Grecian buildings—the main lines of which are horizontal—piled one above another to form steeples, whose lines ought to be perpendicular. The Gothic is the only style, capable of modern application, in which the diminishing steeple can with perfect propriety be employed; for however beautiful an outline at a distance may be, a near inspection of details, formed by many horizontal lines, seldom fails to displease. It must, however, be granted, that some of the steeples of Wren are so extremely beautiful in their outline, that we are compelled to pass over their other faults. The least beautiful examples of Athenian buildings are copied with even more fidelity than the temples, the Propylæa, and the monument of Lysicrates; while the victor's wreaths from the Choragic monument of Thrasylus are employed on the fronts of buildings with which they have no character in common.

But whilst we are making all these objections to the modern imitation of Grecian architecture, it may well be asked—Ought the sublime structures of Greece, and the labours of Revett and Stuart, to have no influence on our style? Undoubtedly they ought. But whilst we have at our disposal the funds of individuals instead of states, and whilst our modern wants require conveniences, which would at once, if introduced, destroy the character and synchronism of a Grecian building, let us not attempt that, which the first step will show is at war with the soundest principle of architectural taste, viz. that all decoration should have its origin in, or show the semblance of, utility. While the Grecian style is quite unfitted, the Italian style is well fitted, to the wants of our climate and manners. It is capable of every variation; it may be used without orders, or may be combined with, and influenced by, the Grecian, without any violent anachronism being apparent. In the style of the Italian palaces, where the orders do not form an important feature in the front, we possess fine examples in the Reform Club House, and in the Manchester Athenæum, both by Mr. Barry. So much has this beautiful style given place to the bad imitation of another unsuited to our wants, that we might suppose our modern architects deemed the presence of a gigantic order, essential to the existence of beauty in a building. Who must not confess, that the most beautiful buildings of Sanmichele, of Vignola, of Palladio, and, in our own country of Chambers, of Burlington, of Talman,* owe an effect to their boldly projecting cornices, to their decorated doors and windows, quite equal to that of the orders, which form so subdued a feature in their fronts? And are not these gazed on with equal delight with the beautiful works of Wren, of Vanbrugh, of Gibbs, and of Hawksmoor, all of whom employed the orders on a large scale, but who used them with more judgment than we have in later times, with all our knowledge of Grecian buildings. But, if the orders are essential, why not, with the classic feeling of the Germans, engraft upon the Grecian a style, which shall be suited to our wants, and yet shall be Greek in feeling and in character—in which we shall recognize no indifferent copies of orders and porticos, showing by contrast the presence of parts necessitated by our climate—in which the spirit of a Grecian architect shall appear to pervade the whole, rather than that the orders should appear the work of an artist, and the doors and

* The talented architect of Chatsworth House, Derbyshire.

windows of a mason and a carpenter. And thus we may find the true value of Grecian architecture; learning between it and modern adaptations to choose a style which shall neither offend by its anachronisms, nor subject us to any diminution of our necessary comforts, designing as Greeks would have designed, had their wants been like ours. Our buildings must be Grecian in essence rather than in form.

E. H.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XXXVII.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. THERE is one circumstance attending architecture at the present day, which has not had the attention and consideration given to it, it deserves; for while so much has been said in regard to the merits and the history of different styles, it has scarcely been noticed that we possess no real style of our own. We may adopt, we may borrow, we may revive, those belonging to other countries, or other times; yet that amounts to no more than the transplantation of them, and, unluckily, the process itself seldom turns out to be any better than that of transplanting *dead trees*. However successful particular buildings may be as imitations, the styles themselves do not take root; they exhibit no symptoms of vitality; they do not *grow*; they put forth no fresh branches: on the contrary, the chances are that some of the old ones are lopped off. By this time it might be supposed Grecian architecture would, if capable of striking root at all, have begun to manifest some vigour, yet it thrives no better than a mere sapless trunk. We began by copying it, we continue to copy it, and are not likely to get any further than copying it. We have got our lessons in it by heart, and repeat them by rote; as to getting them by *head*—that is a different matter, and one of which the idea seems to have occurred to no one. We proceed with it just as far as the extant examples of it will carry us, and not a single inch further. Nearly half a century ago we had Doric porticos *after the Parthenon—anglicized*, indeed, by sculpture being omitted in the metopes, and if we now want a portico in the Doric style, we still go to the Parthenon, or at least to some other established authority, whose columns are as scrupulously copied as if the modern building were intended to be a perfect fac-simile of the ancient one, though it may be impossible to trace the slightest similarity between them except that attending the columns alone. More frequently, too, than not, these last, so far from contributing to style, only serve to show the mutual incongruity between themselves and all the rest, the portico being as little in harmony with the building as the building is with the portico. This system of servile copying—in any other art it would be reprobated as downright plagiarism and piracy—has absolutely stifled the germs of invention, and checked all originality and artistical feeling, which, instead of being encouraged, are actually deprecated as leading to innovation. What a bugbear word is that same "innovation"! Surely, if authority and precedent be of any value, there is abundance of both to sanction innovation, for what is the history of architecture itself, but that of a series of innovations. Without innovation the Greeks would never have advanced beyond their Doric style, and our own ancestors would have stuck fast at their Norman one: or if introduced at all, never would the pointed style have attained that growth, or spread out into that rich luxuriance it ultimately attained, after passing through various stages of—inovation.

II. Well, now that we have again turned to the lancet or first stage of the pointed style, there is no danger whatever of its shooting out afresh. As lately adopted, it is not an infant style of our own: of the promise

of early childhood it possesses nothing, of the hopeless imbecility of second childhood and childishness, much. Are we then to conclude that the inventive powers of architecture are now utterly paralyzed—that as an art it is extinct, and reduced to what is little better than a mechanical profession. The plodders in it are many, those who aspire to be more than plodders, who apply themselves to architecture with the feelings of real artists, are—I will not say how few; but leave it to every one to judge if he himself is among those few in whose favour I throw in that saving clause, lest I myself should be *clawed and clapperclawed* by the whole of them. No one will now cry out; not even Professor Brown, since he will, doubtless, think he must be upon the list of my exceptions.

III. It has been remarked, in regard to despotism, that bad as it may generally be in practice, it is theoretically better than freedom; which doctrine, strange as it may be thought by Englishmen, seems to be that of architects, for they preach in favour of the despotism of authority and of slavish submission to precedents. One of their *oriental* maxims is that what has hitherto served and satisfied those who have gone before us, may very well satisfy us. Of innovation they entertain a most *oriental* horror. Enamoured of slavery, they deprecate artistical freedom, and hug their fetters the more closely when any one proposes to knock them off. Like Russian serfs, they do not care to be emancipated; for they have so long been accustomed to slavery, that to be now released from it would be exceedingly uncomfortable to them. They prefer remaining always in leading strings; since it is far easier to suffer themselves to be so guided, than it would be for them to attempt to guide themselves. Most assuredly it is very far easier to follow *rules* so plain and straightforward that they cannot be missed by any one who is capable of following his own nose, than it is to hunt after and put oneself under the guidance of *principles*—little better than so many will-o'-the-wisp phantoms. Rules, on the contrary, are exceedingly safe, and admirably convenient; they spare a great deal both of time and thought: should you happen to go wrong, the fault lies with them, not with yourself; or rather, as they cannot be otherwise than right, you cannot possibly be wrong. In defiance of every blunder or sin against good taste, you can quote Palladio or some other great authority. There is no architectural vice or absurdity for which some "venerable" and respectable precedent may not be adduced, and if your doings in the Grecian style are reproached for being mawkishly insipid, frigid, common-place, and dull, you can shelter yourself under the very respectable authority of that very classical architect—Smirke.

IV. The more it is examined into, the more untenable will that doctrine be found which refers the origin of the Grecian orders to a timber construction and to the primeval wooden hut. Such notion is absolutely preposterous; not only is it rebutted by the character of the style itself, but is utterly at variance with all historical analogy. The farther we go back into our researches, the more direct evidence do we obtain that the very earliest architectural monuments of all were entirely of *massive stone*, and that so far from resembling even the trunks of trees, the columns were merely upright monolithic blocks, nearly square throughout, with at first very little indication of circular shaft, except in the upper part, beneath the capital, to which it served as stem. Such is the ancient architecture of India, the earliest of all—ponderous, rude, gigantic, and sublime. Borrowed, though not *copied* by the Egyptians, this style underwent a transformation; it was considerably refined; the columns or supporting blocks were made circular throughout, if not invariably cylindrical. Borrowed in its turn, but not *copied* by the Greeks, the Egyptian style underwent a similar process of transformation, and was moulded into the Doric, the cylindrical form of the columns being changed into a conical or tapering one. Such origin plainly accounts for the proportions—so much prated of, and apparently so little understood—of Grecian architecture; whereas they are not at all to be reconciled with the idea of an original timber construction, originating in the brains of "venerable" old women who have written upon architecture, and received as matter of faith by those who find it much easier to believe any nonsense than to examine and inquire. Would even the most *massive* timber

construction have led to any thing like the proportions that characterise the early Doric order? Certainly not; it would have led to quite a different system, both for the columns and the entire structure. That of the intercolumniation would have been just the reverse of what it now is, for the columns would have been three or four times as wide apart. If a timber construction was the type, the character of that type would have been preserved—at least tolerably kept up—at any rate not entirely obliterated. What analogy is there between a timber construction and the ponderous Doric entablature and the *squareness* which prevails in all its members? Oh! but a timber construction, it will be urged, accounts so very “nicely” for the triglyphs. So, then, in order to account for what is something altogether subordinate, and perhaps almost entirely arbitrary, we are to give up what accounts for and explains the style itself, considered as a whole. After all, too, they are accounted for one way just as well as the other. If intended to represent the horizontal beams laid on the architrave, and forming the ceiling between that and the external roof, it does not follow that those beams were of necessity timber ones at first, since we meet with precisely the same arrangement and forms in the ceilings of the most ancient stone constructions. Being ourselves invariably imitators, we seem to be also of opinion that men must have had *ab initio* some express model or type, and that those who contrive and invent must have some pattern to go by.

V. “An *engineer*’s the noblest work of God!”—staggering as it is, such is the doctrine *literally* put forth in a certain quarter, where it is maintained to be the highest honour of our race to be engineering animals. Sages, poets, artists—how do *you* relish it?—you who have so long arrogated to yourselves the topmost pinnacles of human glory? But the world has been mistaken all along, and henceforth mechanics must take precedence of mind, and machinery of art. Having advanced so far in such ultra-utilitarian doctrine, should we not take another step, and be convinced that man himself is but a mere machine—a piece of clever engineering work. Let us hear no more cant about Grecian or Gothic art—let us have no more extacies on the subject of the Parthenon or York Minster—of the Cartoons or the Elgin marbles—the triumphs of Christian or of Pagan art. Henceforth the bridge-builder is to be looked upon as the *Pontifex* maximus of society; and Homers and Phidias, Handels and Raphaels, &c., as a very useless race—quite valueless according to the new ultra-utilitarian principles. We need not, however, inveigh against those principles, because there is no danger of their being at all contagious, for their exquisite absurdity renders them perfectly harmless.

PEN AND PENCIL SKETCHES IN POITIERS AND ANGOULÊME: WITH SOME REMARKS ON EARLY ARCHITECTURE.

By GEORGE GODWIN JUN., F.R.S., &c.

(Continued from page 71.)

Chapter 3.

If a tea-cup be reversed in a saucer, it will convey a very clear idea of the regularly formed mountain, on the truncated top of which stands Angoulême, one of the most ancient of French cities. A low wall encloses a public promenade (once the ramparts) around the whole of the flat summit occupied by the houses, and affords some beautiful views of the continuous valley, studded with cottages and sparkling with streams, at the foot of it, as well as of the adjacent picturesque rocks and hills. In consequence of this peculiar and almost inaccessible position, Angoulême was ever regarded as a safe refuge in troubled times; thus, at that period when the Normans, or North men, ravaged France, burning down churches, and destroying all before them, we find the inhabitants of the neighbouring districts constantly flying to this city, and there defending themselves, although

not always successfully. The approach to Angoulême from Poitiers, from which town it is distant about 78 miles, is very pretty; the peculiarity of its position, and the smoothly flowing Charente which passes it, lending it additional attractions. In the city itself, the chief object of regard is the Cathedral, dedicated to St. Peter,—a structure so extraordinary in its character, that it should be visited by all who view with interest the various shapes taken by architectural skill in the middle ages, the various modifying circumstances which led to this variety in different localities, or who are seeking to learn the immediate source of the style of cisalpine edifices.

Fig. 7.

The above view of the west front, although sketched on the spot,* and correct in the generalities, gives but a very feeble and inadequate idea of this extraordinary façade. The boldness of the sculptures, the size of the five main arches and columns into which it is divided, and the universal decoration prevailing throughout, produce an effect picturesque and striking in the extreme.

In character it resembles Notre Dame de Poitiers (see Fig. 4), and is of that transition period when the semi-circular arch was about to give place universally to the pointed. In width it is about 62 feet. The entrance doorway in the centre was spoiled by injudicious repairs in the last century; formerly it seems there was a porch before it composed of three arches.† In the arcade on either side of the door, the heads of which take a slightly pointed form, as at Notre Dame de Poitiers, and are elaborately sculptured, are the twelve apostles; underneath one of the groups are sculptured knights tilting in chain armour. Above the door is the only window in the façade, now closed, having around it sculptured figures in arcades. Over it, in the centre, is a figure of the Almighty in a *vescica piscis*, supported on a very elegant honeysuckle scroll, and flanked by the symbols of the four evangelists. The intrados of the arch above it, is sculptured

* In October, 1841.

† This was demolished between 1808 and 1810. About the same time, cloisters attached to the building were destroyed.

to represent eight angels. The upper arcade contains a number of circular medallions, with heads upon them. The cornice which terminates the front, and the small turrets at the angles, seem to have been added at the commencement of the 16th century.

There is a small octagon tower at the junction of the nave and transepts, but the bell tower is situated at the extremity of the north transept, and is a very remarkable and beautiful specimen. It rises independently to a great height, and is divided into six stories above the transept, adorned with columns and semi-circular arcades, and terminated with a short pyramidal roof. It may be seen many miles round, rising from the conical hill on which the city is placed, like a high mast, and has a very curious effect. With regard to the details of it, the capitals of the columns are leafed, and indented squares, scrolls, &c., are amongst the chief ornaments of the mouldings. In the top story but one, the arcade would seem to be an alteration or addition, other arches appearing behind those on the face. The uppermost story has large circular pillars at the angles. Withinside the church, the nave, which has no columns, is covered by three large cupolas with plain horizontal bands between each, passing from wall to wall. The bands form a pointed arch, as they do also on all four sides under the centre tower, which is pierced with openings, and serves as a lantern to light the space between the nave and the choir. The choir, which has an aisle on either side of it, terminates with a semi-circular absis, the whole much modernized and injured. The transepts originally presented similar cupolas to those now in the nave. These cupolas are very singular, and are to be seen only in very few instances in France. M. de Caumont, who examined this cathedral in 1834, considers that originally they formed the external covering, but that, finding it difficult to prevent the infiltration of rain water, a wooden roof was afterwards placed over them. In the church of *St. Front*, at Périgueux, the same arrangement has been made; but in the church at Loches, where there are two similar cupolas in the nave, they are still exposed externally and form two cones.*

Touching the foundation of the cathedral, and the age of the present building, it is stated that Clovis rebuilt a church here, and dedicated it to St. Peter. Having been much injured by invading barbarians, it was restored and consecrated in 1017; but ultimately, namely in 1120, was taken down and rebuilt "a primo lapide." Several of the French writers wish to insist that the western front was not pulled down at this time, but that it is a remnant of the structure built by Clovis! This opinion, however, is quite untenable, as the front is evidently not earlier than the 12th century. The church was greatly injured by the Calvinists in the 16th century, as it was also during the revolution of 1793, of which latter time a record yet remains in these words, sculptured over the entrance door, "*Temple de la Raison*."

As another example (in fact, perhaps, constituting with Notre Dame de Poitiers, the three chief examples in France) of a class of buildings little known to us, I annex a view (Fig. 8,) of the extraordinary western front of the church of St. Nicholas, at Civray, situated between Poitiers and Angoulême, and is attributed to the 12th century. It was not drawn on the spot, but is reduced from a very correct engraving of it, published by M. Thiollet, and will serve to give a clear notion of its arrangement. In the upper of the two stories into which this façade is divided, three arches occupy the whole extent, and display some extraordinary bas-reliefs; on the left hand side two figures occupy the place of columns, and support the arches. The doorway in the centre of the lower story is very richly decorated with sculptured figures, as are the arches adjoining the space beneath, each of which is subdivided by two pointed arches, also elaborately adorned. The signs of the zodiac occur more than once on this very remarkable front.

The history of that style of architecture which grew up in Byzantium, after the removal of the seat of empire from Rome by Constantine, is yet to be written. The extent to which it influenced the

Fig. 8.

architecture of Germany, France, and England, was, until lately, very imperfectly estimated, and even now is not sufficiently so. The materials for such a work, which is unquestionably a *desideratum*, are neither few nor slight. Eusebius describes minutely many of the buildings erected by Constantine and his mother,* as does Procopius even more fully those built by Justinian.† Spon and other old travellers give descriptions of many of these edifices, which now no longer remain; and Hope,‡ Mr. Gally Knight,§ M. Albert Lenoir, and M. Mallay,|| have each proceeded a considerable way in elucidating the subject. M. Lenoir, especially, in his architectural course, delivered at the *Bibliothèque Royale*, Paris, in 1838, and since published in the "*Revue Générale de l'Architecture*," has ably sketched out the work required.***

It seems quite clear that Constantinople was the great metropolis of the middle ages, and that at a period when Italy was deeply abased, skilful artists and artisans of all descriptions were to be found in the new city.†† They were accordingly sent for to all parts of the empire, and served to diffuse and make general the style of art there in use. Works in mosaic, if not originated by the Constantinopolitans,‡‡ were made so entirely their own as to become invariably termed *opus Græcum*, and *Bysanteum artificum*; and stained glass, fresco-painting, and other decorations, were brought by them to great perfection. The buildings erected by Constantine were coated with marble, and the cupolas by which they were covered were plated with gold.§§ The

† *De Edificiis Domini Justiniani.*

‡ *Hist. Archit... chap. x.*

§ *Normans in Sicily, chap. xxv.*

|| *Essai sur les Eglises Romano-Byzantines du département du Puy-de-Dôme.*

*** Mr. Willis, in his work on the "Architecture of the Middle Ages," has made some valuable observations bearing on the subject. Dr. Möller's book, "Memorials of German Gothic Architecture," translated by Mr. Leeds, should also be referred to.

†† Gibbon gives a lively description of the magnificence of Constantinople. He says, "Some estimate may be formed of the expense bestowed with imperial liberality on the foundation of Constantinople, by the allowance of about £2,500,000 for the construction of the walls, the porticos, and the aqueducts. *Codinus Antiquit. Const. p. 11.* The forests that overshadowed the shores of the Euxine, and the celebrated quarries of white marble in the little island of Proconnesus, supplied an almost inexhaustible stock of materials, ready to be conveyed by the convenience of a short water-carriage to the harbour of Byzantium." Elsewhere he continues, "A particular description, composed about a century after the foundation of the city, enumerates a capitol or school of learning, a circus, 2 theatres, 8 public and 153 private baths, 52 porticos, 5 granaries, 8 aqueducts or reservoirs of water, 4 spacious halls for the meetings of the senate or courts of justice, 14 churches, 14 palaces, and 4,388 houses which, for their size or beauty, deserved to be distinguished from the multitude of plebeian habitations." Too much haste, however, led to too early decay.

‡‡ An early instance of the use of inlaid work seems pointed out in the description of the palace of Ahasuerus (Book of Esther, ch. i. v. 6, ascribed to the year 521 before Christ), where a pavement is mentioned "of red, and blue, and white, and black marble."

§§ "Cumque templum omne in immensam altitudinem extulisset, vario lapidum genere splendidum reddidit, a solo ad cameram usque marmoris crustis illud operiens. Porro cameram lacunaribus minutissimis operis obducens, totam auro imbracavit." Eusebius *ut supra*, "De constructione martyrii apostolorum Constantinopoli."

* The internal length of the building is 241 feet.

DOORSHEDEABAD IN BENGAL.

TILDEN FOUNDATIONS

earliest buildings were circular, octagonal, or polygonic. Afterwards the exterior became a square, although the internal plan remained a circle or octagon. In Sta. Sophia, built by Justinian, in the erection of which ten thousand men were employed, the internal plan became a cross of four equal sides, known as the Greek cross, and this building was for a long time the model on which other structures were founded.* Elongated cupolas, superimposed tiers of small arcades, columns in recesses, larger arches, or circular-headed openings containing within them two or more smaller arches, and plain square or basket-worked capitals to the columns, are some of the details that were then introduced. "In this new shape," says a French writer, (M. Vitet,) "which in truth causes the exclusive admirers of antique purity to shudder, but nevertheless is entitled to the more indulgent praise of the true lovers of the beautiful, the genius of the old Greek architects awakened; less correct, less severe than before, but brilliant with youth and life—more daring, more marvellous. For the second time the Greeks seized dominion over the grand and beautiful art of architecture: it was from them the Arabs received the secret of it; it was by them that its first lessons were imparted to all Europe."

It is somewhat curious to find that Theodoric, King of the Goths, was educated at Constantinople, and ever retained a love of the arts he had there seen practised.† Ravenna, which was the seat of the Gothic court, vied in magnificence with Rome; and here we find many admirable structures erected both then and in after times. To ascribe this style of architecture and all that it led to, to the Goths, as some Italian and other writers have done, seems absurd, and has long ago been combatted; we must go back to Byzantium for its origin.

In the year 553 the Goths were conquered, and Italy was once more united with the Greek empire. Soon afterwards great part of Italy was seized by the Lombards, who made Pavia the seat of royalty, and raised many structures. To ascribe to them, however, the origin of the style of architecture which prevailed in the mis-called dark ages, seems to be equally erroneous; they but copied and further modified the architecture of Byzantium.

Charlemagne raised many edifices in imitation of Byzantine structures, surmounted with cupolas, in Mayence, Aix-la-Chapelle, and in various other parts of Germany and France, by means of which architecture, which had fallen into abeyance, revived, and received a fresh impulse. The church of St. Front at Perigueux, restored on the original model probably about the 11th century, is one of these. Like the church of Sta. Sophia, the plan is a cross of four equal arms, surmounted by five cupolas on tambours, but which are now hidden externally by a wooden roof. The windows are in threes, connected by a label: each front of the edifice originally terminated with a gable or pediment, but this was in later times filled in, so as to form a straight line round the building, and to receive the wooden roof before spoken of.

Churches on a circular plan, in imitation perhaps of that built by Helena over the Holy Sepulchre at Jerusalem, are not uncommon in France. The church of Charron in the department of Vienne, of which some fine ruins remain, is a good example. The greater part of the structure, as now seen, is of the 11th or 12th century: at the west end are two turrets with conical stone roofs in scales, similar to those at Notre Dame de Poitiers.

To recall the connection with Byzantine architecture apparent in the buildings more specially spoken of in this and the foregoing chapters is, perhaps, unnecessary: the series of small arcades and sculpture in the principal front, the mosaics, the use of external painting, and the occurrence of cupolas, are all fresh in the mind of the reader. In Germany, where perhaps more than in any other country Gothic architecture, as we now see it, was earliest developed, all the older buildings are decidedly Byzantine. In Cologne, especially, the derivation is so strikingly apparent, that none who visit that most interesting city can fail to observe it. In Saxon England, it seems certain that Byzantine architecture was the model chiefly followed. The abbey

church at Hexham, built in the seventh century by Wilfrid, was surmounted in the centre of the transept by a cupola; there were galleries for the women; the arch of the sanctuary and other parts were decorated with histories and images; and the stone work was painted with a variety of colours. The fact that the term *more Romano* was constantly applied to the buildings of this period, does not seem to contradict the position. Constantinople was regarded as a second Rome, its citizens were termed Romans; moreover, we know this description is repeatedly applied by early writers to this very building at Hexham.

We reach truth slowly, and by painfully small degrees: some few detect a fact, others corroborate it in part, information bearing on the point is collected, inferences become apparent; and ultimately a mind arises to lay hold of all that has been said previously, to get rid of the difficulties, and digest the whole into a system. A very few years ago the greatest obscurity prevailed with respect to the semi-circular style, and it was universally called Saxon in works specially devoted to the subject, to distinguish it from the pointed, which was then termed Norman. Writers afterwards, in an equally erroneous manner, as I humbly conceive, termed every building wherein the semi-circular arch was used Norman, without any regard to the country where it was found, or the period which produced it. And even at this time, when so much is being done for the elucidation of architectural history, many still remain with very confused ideas upon the subject, and vacillate between the terms Romanesque, Lombardic, Norman, and Byzantine, often applied indifferently to the same edifices. Let us seek for the truth.

THE NEW PALACE OF MOORSHEDABAD, IN BENGAL.

ERECTED FOR HIS HIGHNESS THE NUWAUB NAZIM,

BY MAJOR-GENERAL M'LEOD.

(With an Engraving, Plate V.)

AT one of the evening meetings at the commencement of the present session of the Institution of Civil Engineers, our attention was attracted to the exhibition of two very splendid water-colour drawings by Mr. John Edward Jones, being perspective views of a palace built in India for one of the subsidiary princes. Upon inquiry we ascertained that this palace had been recently erected, entirely from the designs and under the immediate superintendence of Major-General M'Leod, who, in consequence of an application from us, very handsomely directed Mr. Jones to favour us with whatever drawings we were desirous of having for the service of the *Journal*. For this purpose we selected the plan of the principal floor, and the elevation of one of the principal fronts. We have also subjoined the report of the Committee appointed by the Indian Government to inspect the new palace; it fully describes the nature of the building, and to what purpose the several rooms are appropriated. Without entering into a minute criticism of the architectural character of the building, it must be admitted by all to be one of unusually princely magnificence, and one that will be a lasting honour to the talented General to whom the erection was entrusted.

*Report of the Special Committee of Inspection,
dated Calcutta, 10th Nov. 1838.*

WE have the honour to submit, for the information of his honour the Deputy Governor of Bengal, the result of our proceedings consequent upon the receipt of your letters of the 12th, 19th ult., and without date, received at Moorshedabad, from the Governor General's agent, in regard to the Nizamut buildings at Moorshedabad.

The new Palace is in length 425 feet, by 200 feet in breadth; and of one order of architecture throughout the whole of its exterior, with-

* St. Mark at Venice, built by a Greek architect, was one of its offsprings, as was the Basilica at Pisa, also by a Greek architect.

† Russell's *Hist. of Modern Europe*, vol. i.

out any intermixture of the same on a reduced scale, or of any other order. It stands on a slight elevation, produced by raising the foundation walls three feet above the general level of the ground, and filling up with earth to that height, in a gradual slope, to the extent permitted by the surrounding buildings, and the termination of the premises towards the river, on the banks of which the palace stands—a conspicuous and imposing feature in the landscape from a great distance. The effect anticipated by raising the structure, as just described, has been fully accomplished.

The order employed is the Grecian Doric. It is forty-six feet nine inches in height, having fluted columns thirty-six feet high; five feet six inches in diameter at the base, and four feet one and a half inches at the neck, with corresponding antæ, and an entablature of ten feet nine inches; the whole surmounting a basement of eighteen feet six inches, of which three feet six inches forms the plinth of the building. Over the entablature are parapet walls, varying in height according to circumstances, and ornamented with panels, plinths, and cornices. The projections of the cornice of the order are of stone, having the guttæ and lilies in the angles cut out of the solid. Nothing could be more satisfactory than the execution of the whole detail of what this involves. The Doric order is notoriously of difficult management, when applied to edifices of complicated design, from the necessity of observing the rules prescribed for the introduction of the triglyphs in the frieze of the entablature. In the present instance, with many projections and recesses, tending to create difficulties, there was not discoverable the slightest deviation from what these rules demand; the cornices and mouldings were noticed as being cleanly and sharply cut and defined, and all lines and surfaces, whether of stone or plaster, exhibited the most successful result of much labour and minute attention.

On the south front is a portico of eight columns, ninety-seven feet nine inches in length, surmounted by a pediment twelve feet high, and having a strong trussed roof of timber secured transversely by iron tie-rods. To the north is the entrance portico of six columns, measuring 70 ft. 9 in. in length, with a corresponding trussed roof to the pediment, which rises 10 ft.; in the tympanum of either pediment are the arms of the Nuwaub Nazim, perfectly executed in relieve, and forming a very appropriate and effective finish to the whole.

Leading to the northern portico, is a noble flight of stone steps, commencing in its breadth above from the centre of the end columns, and having a platform stretching out in the same parallel to a width of 24 ft. 9 in., from which, descending, it curves outwards on either side till it ends at its base, in a line extending to the length of 129 ft. There are two intermediate platforms, one of 10, and one of 5 ft. in width; in a line with which last, at the extremities, are well proportioned pedestals with stone slabs, bearing inscriptions (the letters cleanly cut in relief) in English and Persian, exhibiting particulars connected with the erection of the edifice (enclosure No. 1), and in front of these pedestals, on blocks carried out from their bases, corresponding in height and breadth with the last flight of steps, and 10 ft. 6 in. in length, are placed two sphinxes, admirably executed, both as regards the design and workmanship. They are of solid teak, but painted and sanded so as exactly to resemble stone, and form highly ornamental appendages to the entrance in the position they occupy. Iron railing, of a graceful pattern, corresponding with that of the colonnades (rising from which are five lamp-posts on either side, with three on either pedestal below,) surmounts the flight at either extremity. Underneath is a capacious carriage way; and there are three vaulted ranges, two of them open, and one (the lowest) closed in, and forming *Abdarkhânesh* and other useful offices.

To the north front are two smaller porticos (to the wings) of four columns each, and intermediately between the centre and wings on either front, receding colonnades; which also form leading features of the end fronts of the building.

To all the above colonnades, including the porticos, are continuous balconies to the third floor, 4½ ft. wide, of light appearance but of great strength, being constructed of iron beams or cantilevers from 19 to 21 inches apart, inserted in the walls between stones to a depth of

1½ ft., and supported on brackets at intervals, the rest of the material of the floor being of flat bar iron. The floor is composed of tiles, terras, and marble, confined by a plate or band of iron. The railing is partly of iron and partly of teak; the main supports and some of the rails being of the former, upheld by brackets branching from the cantilevers.

The spaces over the doors and windows within the colonnades, as well as those of the treble windows in the exterior walls, are relieved by panels, in which are inserted ornaments of various descriptions, in relief, of good design, and extremely well executed.

There are two open courts in the interior of the building, 72 by 52 ft., finished in every respect in the same style as the exterior, having substantial drains all round, communicating with large covered ones externally, which are carried to a considerable distance, and empty themselves into the river.

Round the exterior of the building there is a platform of the finest masonry, bricken-edge, 7 ft. wide, from which spring small flights of stone steps to the height of the plinth, leading to the entrances in the several compartments of the edifice; outside of which is a roadway or walk, of corresponding breadth, composed of *koah*, 9 in. in depth. The plinth of the building has oval flue openings of 22 by 18 in., furnished with strong iron gratings;—where flights of steps interfere, three of the step-facings in each have gratings, of 18 in. in length, fixed into them.

The interior comprises a basement floor, from 13 ft. to 13 ft. 3 in. in height to the beams; a principal floor, from 21 ft. 9 in. to 22 ft. in height, to the ceilings; and a third floor of the same height as the latter.

Principal floor. The principal entrance is from the north portico into a vestibule 36 ft. by 27 ft., having a geometrical stone staircase at either side, 7 ft. 6 in. in width, with iron railing and mahogany hand-rail, each staircase receiving light from four painted glazed windows. Within this range is a corridor or passage, 12 ft. wide, leading to the wings of the edifice, divided into compartments, and so contrived, that by shutting two doors the communication with the wings is cut off, without any interruption to that between the other portions of the building. From the centre of the corridor a large door opens into a circular room 50 ft. in diameter; to the right and left of which (on entering) is a room 52 ft. by 25 ft.; the three comprising one suite of apartments, separated from the wings by the open courts, (noticed above). The circular room is of the Corinthian order, taken from the temple of Jupiter Stator at Rome. The order is in height 30 ft. 6 in., with pedestals of 4 ft. 6 in. From the entablature, on a line with the frieze, springs a cupola of masonry, with sunk panels, ending in a painted glazed skylight 20 ft. in diameter, the height from the floor to the opening of the skylight being 56 ft., and to its apex 62 ft. The room is decorated in its circumference by four large covered recesses, over which are long panels, eight pilasters, and four large doors; over which last are oval openings occupied with pierced screens of arabesque, cut in single slabs of stone. All the mouldings and compartments are richly carved and ornamented, in conformity with the rules of the order of which the apartment is composed; and, whether as regards the effect of the whole, or the exquisite finish of the details throughout, it is impossible to speak too highly of what has been accomplished. There is nothing to add, and nothing to alter: the architect and builder have done their work perfectly. To the south of the above suite is a grand colonnaded saloon, measuring 187 ft. 6 in. in length, susceptible of division at pleasure into three apartments, by means of sliding doors 18 ft. 2 in. wide, the leaves sliding into cases, faced on both sides, from the bottom to the top, with mirrors. The general width of this saloon is 55 ft., the centre space within the bases of the columns being 25 ft. Beyond either extremity of the saloon is a geometrical stone staircase, 5 ft. 3 in. wide, with railing, as before described, communicating with the apartments of the wings.

The wings do not correspond internally with each other: both are divided into apartments of various suitable dimensions, each having a spiral stone staircase at either corner, with baths, dressing rooms, &c.

With the exception of the circular room, the interior of the whole of the principal floor is of the Roman Doric order.

On the third floor the dimensions of the several apartments necessarily correspond with those immediately below, just described, excluding the circular room, which comprehends both floors. In this third floor also is the same arrangement of the saloon as that described for the principal floor, but the order throughout is the antique Ionic, 19 ft. high, with fluted columns, pilasters, &c., surmounted by a coved ceiling rising 2 ft. 9 in.

The whole of the apartments in both these floors are ceiled with canvas, or teak wood frames, through which are fitted into the beams strong brass hinge-hooks for punkabs, and brass for lamps or lustres, to an extent ample for every purpose of use or ornament. In both floors the doors are painted in imitation of different woods (satin wood, mahogany, oak, maple, &c.) and highly varnished; and, with a few exceptions (in the minor apartments of the wings) they are fitted with plated locks, bolts, and hinges, and hand-guards; also on the principal floor. All the apartments in the wings of both floors are coloured in distemper, in light tints of various colours; and the walls, as high as the surbase of the vestibule, and four staircases, are painted in imitation of marble; all with very good effect. There are twelve fire-places, with carved mantel-pieces of teak, also painted and varnished in successful imitation of rare marbles. The floors of the whole of the public apartments of the principal story, including the vestibule and landing places of the great staircases, are paved with polished marble; and those of the corresponding apartments in the third story, with the landing places of all the four staircases, are laid with teak boarding. The whole of the public rooms in both floors, and the columns in the wings, are finished with polished stucco, in imitation of the Madras chunam; and it may here be observed, that the flutings and finishings of all the columns, exterior and interior, are remarkably well defined, and evenly and sharply wrought; a completion very rare, where brick and plaster are the materials, in houses even of the highest pretensions in this country.

The basement floor is finished in a plain style, having a simple moulded band under the beams and no ceilings. The doors and windows are of appropriate substantial construction, fitted with brass locks, bolts, and hinges, and painted plainly. Under the circular room (of paragraph 15) are four strong lock-up closets for treasure, plate, jewels, or other articles of value, with a large open space for a guard. In the arches of the treble windows of this floor, fifteen in number, are coloured fan-lights. In the west wing is a steam-bath, complete in all respects, executed subsequently to the erection of the building, as we were informed by Colonel McLeod, at the particular desire of the Nuwaub Nazim. All the exterior colonnades and porticos in the basement and principal floor, as well as the vestibule and staircases of the basement, are paved with stone.

Pleasure Grounds.—Kosah roads, twenty feet wide, have been constructed, and well rolled, in all that portion of the ground about the Palace which has yet been cleared of old buildings; the banks of the river have been sloped off and sodded throughout the whole extent (with the exception of a very small portion, for which it seems earth was not procurable) and stone posts have been inserted along the top, as fastenings for boats. The whole of the ground (cleared) has been smoothed and grassed, and completely drained. At a short distance, in front of the Palace, is a handsome sun-dial, five feet in diameter, a surplus stone so converted by Lieut. Cunningham; it rests on a pillar based on stone steps, and forms a useful and appropriate appendage to the premises. A substantial stone ghat, fifteen feet wide, has been constructed near the Palace for the convenience of the Nuwaub, and at about 800 yards to the south of the Palace a large *Noubkahné* gateway has been erected, as an entrance to the grounds in that direction. As it was not immediately in view, there did not appear to be any objection to its being built in a style of architecture adapted to its purpose, and the Asiatic or Turkish has been adopted.

In concluding this head of our report, it seems proper to advert to the fact of this edifice, in all its departments, having been constructed and completed by natives of the country; the only exceptions to which

remark are in regard to the painting and glazing, which portions of the work were executed by professional Europeans. The expressions of approval which will have been found interspersed with the preceding details, were elicited by particular features of the building under review, inviting a more peculiar attention from their importance, or the effect produced by them on the eye of the observer; but they are equally applicable to every part of the structure, which, whether considered as a work of art to be admired for its exceeding beauty, or as an example of skilful labour applied to the practical combination of excellent materials, reflects the highest credit on the architect, and all subordinate to him, concerned in its erection. The late rainy season was one of uncommon violence, and had just closed when our survey was made, and the soil far and wide was either inundated or saturated with moisture. Nothing could have more searchingly tested the strength and solidity of a newly erected edifice; but not a crack or symptom of yielding was to be seen, externally or within, throughout the whole extent of this fabric; and we conclude our remarks upon it with the expression of a grateful anticipation, that a lengthened durability awaits what we have represented as so pre-eminently worthy of a lasting preservation.

In conclusion, we would here recapitulate, in a few words, the opinion to which our inquiries have led regarding the three points to which reference is made in the second paragraph of our report. As to the execution of the works, our verdict, after a careful examination of all that presented itself to our view, is one of unqualified approval and commendation.

REID'S FLOATING BREAKWATER.

FLOATING BREAKWATERS are at the present moment occupying much of the public attention, which has induced me to turn my mind to the subject: the result of my labours I submit to your notice. The objection of a gallant officer in the House of Commons to floating breakwaters, because chain cables would last only a few years, is but a trifling objection. If the success only depends upon the cost of cables, the ships and property, not to speak of lives saved, would fully compensate the country for occasionally laying down new moorings.

EXPLANATION OF ENGRAVING.

A is an arched frame of timber in thicknesses, 6 ft. high in the centre; B frame of timber bolted together, 2 ft. square, and 20 ft. long on the chord line; C sloping frame of timber, 1 ft. square, secured with iron straps, bolts, and stays, and protected at the point by iron shoes; D inclined plane on shutter 24 ft. 6 in. long, laid to an angle of 35°, with planking laid diagonally and bolted to a framework of timber, the planking need not be laid close, there may be a space of 3 or 4 in. between; E iron cable; F bridle, and G chain for lifting shutter; H bit or head to which the cables are secured.

If the depth of the wave be 9 ft. below the chord bar of the arch, there will be 6 ft. (perpendicular) of the shutter below that, the inclined plane will underrun the wave, and the arched frame work above will offer a gentle resistance for the wave to fall upon, and distribute itself harmless. There will be no strain upon the hinges, the cables

being secured to bits in the centre of the raft. When the sea strikes the front of the inclined plane, the framework will yield, and the hinges will prevent that sudden check which the cable tightening would give to the work. Were they not there, the frame would almost instantly resume its place; the buoyancy of the shutters takes all weight from the hinges. The principal use of the hinges to the shutters is for the more easy recovery of the moorings. A small chain attached to the shutters will enable them to be weighed at pleasure; when at the surface they are easily hung to lighters. The iron plates on the shutters under the moorings are to prevent the wood being chafed away by the friction. Each shutter is proposed to be 30 ft. long; the raft can be increased to any height, though 60 ft. broad would be sufficient for the heaviest sea that ever ran. Unlike a beach, there would be no back run of water; and a raft of such breadth would have the effect, from its own hold in the water, of rendering the whole front stationary, at least this, I imagine, would be so. I should think 20 ft. perpendicular depth would also be deep enough for any weather. One of moderate dimensions, tried in a moderate sea, would prove its efficacy. It is an idea formed after considerable reflection, upon seeing plans of others, and hearing objections urged. If it should prove successful, 'twill be a double pleasure; and the lives it may be the means of saving will not be the least portion of such gratification.

March, 1842.

ON THE ECONOMY OF FUEL IN MARINE ENGINES, AS PRODUCED BY EXPANSION.

BY J. G. LAURIE.

IN prosecuting the investigation of expansion, I now come to consider it with reference to economy of fuel, as applied in marine engines. In former numbers of this Journal I have investigated its effect in locomotives; but important as economy of fuel is in them, it is of vastly greater importance in marine engines, the result in the one case being only a diminished expenditure, and in the other the accomplishment of passages otherwise quite unattainable. In sea-going steam vessels, subjected to varying weather and tempestuous voyages, the application of expansion is as beautiful in theory as beneficial in practice. By its means the power of the engine both statical and dynamical is most beautifully adapted to the necessities of the vessel, for by extending or contracting the degree of expansion in favourable or adverse weather, the mean statical force of the engine and the resistance of the vessel are, within extended limits, exactly proportional; and in each case the dynamical power is greatly increased over what it otherwise could be, and that too in the way (in the one case being by increased statical force, and in the other by speed,) in which it is most available.

In marine engines there are two means in use for effecting expansion; the one being by the D valve, and the other by a separate or expansion valve, which in some engines are used singly, and in others jointly.

The slide valve, as wrought by an eccentric, and constructed with only sufficient cover to keep it tight, seems admirably fitted to the purpose for which it was introduced, but does not seem so capable of carrying out the principle of expansion, for, in the first place, it does not afford the means of varying the extent of expansion, and, in the next place, when expansion is to be carried to any considerable extent, it opens and shuts the ports in a manner that has the effect of virtually diminishing the size of the engine. In proof of this, by referring to my communication in No. 47 of this Journal, it will be found proved that, if A B C D be a steam cylinder, A D the stroke of the piston = $2d$; the radius of the eccentric = a ; the cover of the valve on the steam side = c ; distance from commencement of stroke to commencement of expansion = a' ; distance from commencement of stroke to termination of expansion = b ;

$$a' = \frac{2d(a - c^2)}{a^2} = 2d \times (1 - c^2) \text{ when } a = 1 \quad b = \frac{a^2 d + d\sqrt{a^2 - c^2}}{a^2} =$$

$$d + d\sqrt{1 - c^2} \text{ or for a particular and perhaps an extreme case, take } c = \frac{3}{4a} \text{ and then } a' = 2d \times \frac{7}{16} \text{ and } b = 2d \times \frac{3 \cdot 3}{4} \text{ which proves that when}$$

there is cover on the steam side only of the valve, and when that cover is sufficient to expand the steam from 1 to 1.9, the whole available volume of the cylinder for receiving the steam from the boiler, and

for expanding that steam, does not exceed $\frac{3 \cdot 3}{4}$ of the cylinder, nor does

it come to be quite so much as that, for at the same moment that expansion terminates on the one side of the piston, compression of the enclosed vapour commences on the other, which can be viewed either in the light of detracting from the power already developed by the piston, or of diminishing (which it does in reality) the available part (a') for receiving fresh steam from the boiler. If less cover be given to the valve, the evil here pointed out is also less; and when the cover is small, it seems to be quite overbalanced by a property which shall be hereafter explained. But if, on the other hand, greater cover be given them, it is more than proportionally increased, and comes to be of serious amount; to avoid which the valve is frequently constructed so that it shall have cover on the eduction side as well as on the steam side. If these covers be equal, then at the same time that the steam is cut off from the side of the piston, the eduction is cut off from the other, in consequence of which, although the available part (b) is increased by giving cover to both sides of the valve, the available part (a') is decreased, and, in addition, the period of time for which the educting side of the piston is in communication with the condenser is greatly shortened; if, however, the cover on the eduction side be less than the cover on the steam side, this effect of compression of the enclosed vapour will be diminished, and the period of time for condensation lengthened, but so will also the available part (b) of the cylinder be diminished. Hence betwixt the advantage of increasing the part (b) of the cylinder, and the disadvantage of diminishing (a') and shortening the period of time for condensation, there is some extent of cover of the eduction side of the valve, which shall in the greatest possible degree secure the one and avoid the other. The exact magnitude of this might (but with great difficulty, from the nature of the analysis, which is lying before me,) be ascertained analytically; but though it were ascertained with all conceivable precision, still the plan of expanding by the slide valve has the effect of diminishing the available size of the cylinder, and, therefore, to employ the steam produced by a given boiler, that steam being expanded to a given extent, will require a cylinder, and, consequently, an engine, larger when that engine expands by the D valve than when it expands by a valve which does not diminish the available volume of the cylinder, which, even though there were no other reason, would, in engines of considerable magnitude, in which alone expansion is much used and is most serviceable, prevent the adoption of expanding by the slide valve, and give a decided preference to a separate one being employed for the purpose.

To expand by a separate or expansive valve there have been almost numberless schemes, the principal of which are throttle, slide, and conical valves, of various constructions and variously situated, each of which has in its turn had some claim to superiority over every other. The great aim of the various plans seems to have been to cut off the steam close to the cylinder ports, for the attainment of which, in many cases, means are resorted to that are both difficult of execution and troublesome to keep in order. The evil produced by placing the expansion valve at some distance from the cylinder port is two-fold. In the first place, such an arrangement fixes a limit to the extent of expansion depending on the ratio of the volume of the cylinder to the volume of the steam betwixt the cylinder port and the expansion valve; and the next place, the effective power of the steam throughout the stroke (or in other words, the area of the indicator diagram,) is diminished, the amount of which diminution may be thus estimated. Let volume of steam cylinder = a ; volume of steam betwixt cylinder port and expansion valve = b ; pressure of steam at commencement

of expansion= p ; pressure of steam at termination of expansion= s .

Then, efficiency of whole stroke of piston= $s(a+b) \log. \frac{p}{s} + 1 - bp$
or put $a=1$ $p=1$

and then efficiency of the whole stroke = $s(1+b) \log. \frac{1}{s} + 1 - b$

To find from this what would be the efficiency were the expansion valve close to the cylinder port, put $b=0$; and hence—

Efficiency when valve is close to cylinder port= $s \log. \frac{1}{s} + 1$

Do. when valve is at a distance (b) from do.= $s(1+b) \log. \frac{1}{s} + 1 - b$

which formulæ assign the amount of injury entailed upon an engine by any given position of expansion valve, and, therefore, the amount of preference due from this cause to one valve over another. But by substituting for (b) its value, in practical cases we find that the amount of the injury is by no means of sufficient importance to warrant the exclusion of all expansion valves that do not cut off close to the port; and by making a comparison of the three, namely, the slide inserted betwixt the D valve and the face of the cylinder, the slide valve in the inside of the cylinder steam jacket, and the double-beat conical valve (the three which seem to be at the present time of the greatest importance). Taking into consideration simplicity of arrangement, simplicity of execution, facility to keep in repair, and efficiency of action, including facility of altering the degree of expansion, we are led to believe that the double-beat expansion valve is the one which, in the aggregate, is the best. This valve (b) in well constructed engines does not exceed one-thirtieth; but as an average case, take one-fifteenth of the volume of the cylinder, and by substituting this value of (b) we find the loss of effect of the steam from having one-fifteenth of the whole volume of the cylinder betwixt the cylinder

$$0.06 \cdot s \times 0.06 \cdot \log. \frac{1}{s} + 1$$

port and the expansion valve to be—

$$1.06 \cdot s \log. \frac{1}{s} + 1 - 0.06 \cdot$$

or when $s=\frac{1}{2}$ to nearly $4\frac{1}{2}$ per cent. of the whole power developed by the engine, which points out the propriety of putting the valve as close to the D valve casing as possible.

Adopting then the double beat conical valve, the economy of fuel as produced by expansion may be thus estimated. Let the volume of steam cylinder when there is no expansion= a ; volume of steam betwixt cylinder port and expansion valve= b ; pressure of steam at commencement of expansion= p ; pressure of steam at termination of expansion= s . Then $s:p::a$: volume of cylinder when expansion

is carried to extent (s) $\therefore$ increased volume of cylinder= $\frac{ap}{s}$ but (b)

must be taken proportional to the volume of the cylinder $\therefore a:\frac{ap}{s}$

$\therefore b$: increased volume betwixt cylinder ports and expansion valve

$\therefore$ ditto = $\frac{bp}{s}$ and by substituting these values of

(a and b) in the formula $s(a+b) \log. \frac{p}{s} + 1 - bp$, we find that with

the expansion (s) the efficiency of a given quantity of steam is $(ap+bp) \log. \frac{p}{s} + 1 - \frac{bp^2}{s}$. Put in this $a=1$ $p=1$ $b=\frac{1}{15} \times$ volume of

steam cylinder, which, in well constructed engines, it will not exceed, and efficiency = $1.04 \times \log. \frac{1}{s} + 1 - 0.04 \times \frac{1}{s}$

Let $s=1$ which is the case of no expansion, and efficiency = 1

" $s=\frac{1}{2}$ which is the case of the steam

being cut off, when stroke $\frac{1}{2}$ finished & efficiency = 1.285

" $s=\frac{1}{3}$ " " " " = 1.4

" $s=\frac{1}{4}$ " " " " = 1.68

" $s=\frac{1}{5}$ " " " " = 2.06

" $s=\frac{1}{6}$ " " " " = 2.32

" $s=\frac{1}{7}$ " " " " = 2.88

And hence the following conclusions:—

If the work done by a ton of coal when the steam is used without expansion be represented by unity, the work done by the same fuel when the steam is used expansively to the extent of reducing its pressure to $\frac{1}{2}$ of its original pressure, is represented by 1.285.

And when to the extent of reducing

its pressure to	$\frac{1}{2}$	the work is represented by	1.4
" " " "	$\frac{1}{3}$	"	1.68
" " " "	$\frac{1}{4}$	"	2.06
" " " "	$\frac{1}{5}$	"	2.32
" " " "	$\frac{1}{6}$	"	2.88

In a former part of this paper it was mentioned that it is advantageous to construct the D valve with a small extent of cover, notwithstanding its effect of diminishing the available volume of the cylinder, and for the following reasons:—when the piston of the steam cylinder is near either end of its stroke, the effective leverage of the crank to turn the paddle shaft is small; and although the amount of power developed by a given quantity of steam is at every part of the stroke precisely the same, yet, in consequence of the varying leverage of the crank, that portion of the power applied to overcome resistance at the extremity of the paddle wheel arm is by no means the same, being diminished at no two parts of the stroke by the same quantity, to overcome friction; for as the leverage of the crank decreases, that of the friction on some of the journals, in reference to the power, increases. And beyond a certain point, it is very questionable if (the engine being deprived of all momentum,) any amount of power that could be applied to the crank pin would bring the crank to the perpendicular position, and therefore for a certain portion of the stroke at each end, the steam not only does not increase the efficiency of the engine, but detracts from it, by the amount of power necessary to overcome the friction produced by its application; and hence the propriety of the plan adopted by some makers, of constructing the D valve with so much cover as causes the eduction to commence before the termination of the stroke, and the average vacuum effected before the return stroke has advanced to that point when the steam begins to be effective. The extent of cover necessary to effect this object is quite beyond the power of analysis to assign, and perhaps no two engineers have from their observation arrived at exactly the same conclusion; but I should say that constructing the D valve with only sufficient cover on the eduction side to keep it tight, and with from 0.25 to 0.3 of the breadth of the port on the steam side, would probably with the average of cases be not far from the truth, with which construction the cylinder would be in communication with the condenser from $\frac{1}{15}$ to $\frac{1}{10}$ of the whole time, for eduction before the termination of the stroke.

Greenock Foundry, 15th April, 1842.

ON THE SKEW ARCH.

An analytical investigation of the principal properties of the Skew Arch. By a Workman.

LET A B C D, $a b c d$, be the plan of the semicylindrical arch, the elevation on the skew of which is represented by A G B b F a; draw a K perpendicular to the axis H E R, and G E perpendicular to A B, and N n' parallel o a K; let the spirals, which commence from n n', intersect the skew elevation in the points S s, join S and s, and produce this line to meet the axis G E produced if necessary in O, the line E O is stated by Mr. Buck to be a constant quantity, the investigation of which will form the subject of this paper.

The subject of inquiry seems to demand the complete solution of the two propositions.

First. To determine the intersections s and S of the spirals commencing at n n', with the skew elevation a F b and A G B.

Second. To determine the point where the line joining S and produced meets the axis G E.

fig. 1.

Fig. 2.

Let LSl and Msm be two square sections at right angles to the axis, and passing through the points S and s respectively.

$bK=b$ which is called the obliquity of the bridge.

a = axil length (see Buck on oblique arches).

$rR=EF, EG$ radii of the semicylinder respectively.

$w=HN, n=3.14$, &c.

$\sqrt{sV}m=X$ and $\sqrt{SV}l=X'$.

Let x, y, z , be the rectangular co-ordinates of the point s , origin at H , Z measured vertically, and x on the line HK .

First for this point s we have the following equations:—

$$x = r \cos. X, \quad y = w + \frac{aX}{n}, \quad Z = r \sin. X \quad (1)$$

These equations are too obvious to need any further explanation.

Next, to find the equation of the elliptical face aFb , let $x' y' z'$ be the rectangular co-ordinates of any point in this face, referred to the same axis and origin as before, Y the angle made by a section passing through this point parallel to the section LSl

$$\therefore x' = r \cos. X, \quad y' = \frac{(1 + \cos. Y) b}{2}, \quad z' = r \sin. X \quad (2)$$

* This equation is obtained in the following manner:—

$$y' = \tan. \angle E s H \times (r + r \cos. Y) \text{ but } \tan. \angle E s H = \frac{b}{2r}$$

$$\therefore y' = \frac{(1 + \cos. Y) b}{2} \text{ as stated above.}$$

At the point of intersection of these two lines, namely, the spiral and the ellipse, which is formed in the skew elevation, we must have the following obvious conditions:—

$$x = x', \quad y = y', \quad z = z' \quad \therefore X = Y$$

$$\text{Consequently } w + \frac{aX}{n} = \frac{(1 + \cos. Y) b}{2}$$

$$\text{By reduction we have } x - \frac{n b}{2 a} \cos. X = (b - 2 w) \frac{n}{2 a} \quad (3)$$

the equation for the intrado.

The equation to the extrado is a similar one to that of the intrado, viz.—

$$X' - \frac{n b'}{2 a} \cos. X' = (b' - 2 w') \frac{n}{2 a} \quad (4)$$

where $b' = b + 2 K K'$ and $w' = w + K' K$

$$\therefore b' - 2 w' = b - 2 w + 2 K K' - 2 K' K = b - 2 w$$

by similar triangles $2 r : (R - r) :: b : K K'$

$$\therefore 2 K K' = \frac{R b - b r}{r} \therefore b' = \frac{b R}{r}$$

Substituting these values in equation (4) we shall have for the equation of the extrado—

$$X - \frac{R}{r} \cos. X' = (b - 2 w) \frac{n}{2 a} \quad (5)$$

Now it is easily seen from equations (3) and (5) that the following relation subsists:—

$$(X' - X) \frac{2 a r}{n b} = R \cos. X' - r \cos. X \quad (6)$$

If we assume X any arbitrary quantity along the intrado of the skew elevation, the solution of equation (6) will give us X' the corresponding extrado.

But it is easily seen that this equation cannot, by the present state of analytical science, be generally solved. The best mode of effecting an approximate solution is by the aid of Lagrange's theorem, as given by Lacroix (see his calculus differential and integral); but this will be rendered unnecessary by the aid of the following proposition:—

To determine the point O , where the line joining the points S and s intersects the vertical radius, draw st, ST , perpendicular to GE respectively, and call $\sqrt{a b K} = \theta$

$$ts = r \cos. X \times \text{cosec. } \theta \text{ and } TS = R \cos. X' \times \text{cosec. } \theta$$

by similar triangles $TS : ts :: TO : tO$

$$\text{that is } tO = tE + EO = \frac{ts \times TO}{TS} = \frac{ts}{TS} \times (TE + EO)$$

by substitution and transposition we have as follows:—

$$EO = R \times r \left(\frac{\sin. X' \cdot \cos. X - \sin. X \cdot \cos. X'}{R \cos. X' - r \cos. X} \right) \\ = R r \times \frac{\sin. (X' - X)}{R \cos. X' - r \cos. X} \quad (7)$$

by substituting the value of (6) in (7) we have—

$$EO = \frac{n b R}{2 a} \times \frac{\sin. (X' - X)}{X' - X} \quad (8)$$

It will readily be seen from equations (3) and (5) that X' is always greater than X between the limits $X=0$ and $X=\frac{n}{2}$; but $(X'-X)$ con-

stantly diminishes from $X=0$, then a maximum to $X=\frac{n}{2}$ where

$(X'-X)=0$. From this it appears that EO is not theoretically a constant quantity; but in the construction of bridges $(X'-X)$ when at its maximum is so small,* that we may safely infer $\sin. (X'-X) = X'-X$,

$$\therefore EO = \frac{n b R}{2 a} \quad (9)$$

a constant quantity: this is the greatest value that EO can possibly attain.

* All the lines which are made use of in the foregoing investigation will, I think, be perfectly understood by those who have read the first chapter in Mr. Buck's Treatise on the Skew Arch.

ON BEAM AND DIRECT ACTION ENGINES.

"Non omnia possumus omnes."

SIR—Perceiving in your excellent journal a controversy of considerable importance, relative to the Beam and the Gorgon engine, I am induced to offer a few remarks thereon, placing them at your perfect disposal; and at the same time allow me, in mere good humour, to beg that we conduct our arguments in gentlemanly style, and avoid as much as possible cause for irritation, especially all harsh expressions not necessary to the elucidation of the subject. I allude to the opening paper of Vulcan, and reply of Mr. Pole, whose terms "misrepresentation and fallacy," I object to, especially in his first paragraph; he should allow your readers to draw their conclusions on these points and not prejudge the question.

As a dispassionate member of the profession, one not more wedded to the beam engine than other constructions, when such can be shown advantageous in their application, I pen the following remarks without prejudice, and will endeavour to carry out the principles recommended in my first observations, and to argue upon nothing but facts which have been published upon good authority, and which, I believe, cannot be disputed with fairness. After a careful perusal of both papers, and full consideration of their contents, I have come to the conclusion that Mr. Pole has not materially affected the position of Vulcan, or denied his chief points; why, it shall (with your permission) be my object to show. Vulcan's position appears to me to be this:—

1st. That the Gorgon engine is not new, as it regards the direct application of the power, and further that the credit due to the Messrs. Seaward is not equal to their claim, considering the chronology of its introduction.

2nd. That a saving of nearly one-half in space is not correct.

3rd. That a saving of 25 per cent. on the beam engine in weight is not founded on fact, and also that the weight given to the Government has been considerably exceeded.

4th. That the guaranteed consumption of fuel at $6\frac{1}{2}$ lb. per horse per hour, is far from fact exhibited in practice.

With regard to the first point, Mr. Pole (am I right in supposing he writes "by authority"?) grants that the application of the "direct action" is not new, having been applied in the Tourist and United Kingdom, and the only question remaining is the comparative improvement of the Gorgon's on these, I may say at that time the only generally known (in this country) constructions of *direct engines*. Now, in my humble judgment, in considering this we should take into account the period at which they were brought forward, and make allowances for the infant state of marine engineering when Gutzmer designed his 50-horse engines subsequently placed in the Tourist, and that we should not omit to consider the great experience and practice we have all obtained from that period up to the year 1837, when the great light of the Gorgon engine burst in upon us.

Apart from the early period in which Gutzmer brought forward his direct engine, it should be recollected that the Tourist was a very small vessel—I say *mas*, for she has been considerably lengthened—very shallow in her hold, quite flat in the bottom, and small draft of water, circumstances the very opposite of the Gorgon and Cyclops. The engines, in plan, were like Mr. Penn's oscillating engines, having one air pump and one condenser, the former wrought by a *cranked shaft*; so far Vulcan is right, for I feel assured Mr. Pole does not suppose the similarity was assumed, in workmanship or proportion. The stroke was 3 feet, and cylinder 40 inches, and the connecting rods were 2 feet 9 inches long,—less than twice the crank. I apprehend little difference of opinion will exist as to the cause of their imperfect action. It may be asked, why was this? I answer, Gutzmer had no alternative, other than making his wheel much too large for the stroke, and had he even put aside this objection, he must have brought his shaft on deck, which, in those times, would have raised a host of prejudices, and somewhat risked the insurance of the vessel. He had to contend with imperfect machinery, bad lathes and tools, and men unacquainted with their work, and many other things too numerous to mention, but too well known to projectors of olden time. It is not too much to say that the principal of these difficulties have been overcome for some years. Thanks to the late Mr. Maudslay, to Nasmyth, to Whitworth and others, we have arrived at a wondrous perfection in the executive department. I am almost tempted to say, the difficulty now lies not in the *execution*, but in the *invention*. How many schemers can tell a contrary tale!

Possessing these views, in conjunction with Vulcan, I cannot give to the revivifiers of a dormant scheme any credit of "conception or invention"; but that some merit is undoubtedly theirs, let us see how far it goes.

The Tourist was a small vessel of 300 tons, 23 feet beam, and 14 feet depth in hold; draft (loaded for the voyage), about 8 feet 6 inches, or 9 feet. Compare this with the Gorgon, a ship of 1050 tons—37 feet beam, 23 feet depth in hold, draft about 15 feet. Let us transpose the cases, and suppose Gutzmer to have flourished now and Seaward then: is it not reasonable to suppose that the acute Scotchman, possessing all the knowledge of modern improvements, would have carried out his principle in a very different manner? It should be recollected that large "men-of-war" steamers were not then thought of, and also that the "direct principle" is not, and never can be applied to vessels with a small draught of water, with any useful effect: so far, we are where Gutzmer left us. Powerful steamers are emanations of modern ingenuity, and it does not follow but that Gutzmer would have made his principle as "efficient and applicable on a large scale" as the Messrs. Seaward, had the circumstances of the times been in his favour.

There is another point in which I wish this question to be viewed. Any claim as to the "direct principle" having been conceded, it only remains to show how far there is *originality* in the arrangement or mechanical adaptation of the Gorgon engine, and I think I shall be enabled to show that this belongs, equally with the "direct principle," to a time antecedent to the Seawardian age.

Those of your readers who possess a copy of Gregory's *Mechanics* are referred to plate 23, fig. 10, and to the letter-press, vol. ii, p. 85, "Parallel Motion." In the former they will see an exact delineation of the Gorgon engine, and in the latter the worthy Professor informs us, after a full exposition of the principle, "that this motion, as well as fig. 8 (the common bridle motion) were devised by Mr. William Dryden, a mechanic, whose ingenuity needs not our encomium," p. 286, art. 3. Now, I am not prepared to say when Dryden invented it, but this is certain, that it was antecedent to Gutzmer, for he copied the motion No. 8 (the bridle motion) in the Tourist's engines, and by a curious coincidence his other invention was adopted in the Gorgon engine. The merit due to the Messrs. Seaward is that of "adapters"; to that they are justly entitled; they have shown great tact and judgment therein.

In criticising Vulcan's remarks upon the dimensions of the Gorgon engine, I scarcely think Mr. Pole is fair in putting forth a small table of the *lengths of engine-rooms*, as a criterion of space occupied, although his statement is perfectly correct. It is well known in the profession, that the engineer is not always consulted as to the distance between his bulkheads. It is often increased to make room for stores, duplicates, accommodation for engineers, &c. Sometimes the distance is increased by the shipwright, by caprice of the engineer, who does not wish to be "cramped" in manipulating his engine. We may also say, in large men-of-war it is not advisable to concentrate such great weights, but to spread them as much as is consistent with the accommodation of the crew, and the purposes of war. To my personal knowledge, this feeling has lengthened many engine-rooms several feet. In private trading vessels, I grant, the machinery should be as compact as possible, passenger accommodation and hold being of first-rate importance.

Now, in Mr. Pole's table, the vessels having *beam engines* are Hydra, Medea, and Vivid, the engine-rooms of Hydra and Gorgon being of equal length, viz. 62 feet, that of the Medea 60 feet; and it should be recollected that these vessels were fitted without the smallest idea of competition in this respect. Had it been so, I have no hesitation in saying that that of Hydra could have been reduced four feet without the slightest inconvenience; and Medea in the same proportion. Those of your readers who know the vessels are aware this is not mere assertion. But I will endeavour to show that the engines of the Hydra might be increased to 160 horses each (now 110), *without any increase of space*; and more, that a *beam engine* of the Gorgon's proportions may be constructed to occupy space as shown in Vulcan's diagram, and to weigh (with water in boiler) not more than 300 tons.

Having, therefore, I hope, explained why we should not take length of engine-rooms as conclusive evidence of excellence, we must recur to Vulcan's original position, and take the *bare* space occupied by the engine, especially as Mr. Pole has thrown aside all other portions of the machinery: on that very ground I am prepared to meet him.

First, I will show that the engines of the Medea and Hydra may be extended to 160 horses, without longitudinal increase of space in the latter, and a slight lateral increase in the former. The Hydra's engines are 110 horses each; cylinders $55\frac{1}{2}$ in. diameter, and 5 feet stroke; length between centres of cylinder and shaft 15 feet, or 3 times the stroke. I believe this to be Boulton and Watt's usual practice, exceeding in this particular most other makers, (Maudslays, for instance,) and may here observe Mr. Pole appears to have overlooked Vulcan's statement, that he took Mr. Watt's data to prevent cavil, and see his computation of Gorgon power, namely, an assumed pressure of "seven

pounds," and 33,000 lb. lifted one foot. My calculations are made on the same basis. Referring to Weale's Tredgold, vol. ii, plates 33 and 34, engines of the Nile, (being exactly similar to the Hydra's,) plate 34 on the plan, shows the distance between the ends of the main levers to be 6 feet 4 inches, consequently there is room for a cylinder of that dimension over the flanges. Taking Mr. Watt's data, a 5-foot stroke should make 21½ strokes per minute, or 215 feet. This at 33,000 lb. is equal to a 67-inch cylinder to produce 160 horses, and if we allow 4 inches each side for the joints and flanges, we have $67 + 8 = 75 = 6 \text{ ft. } 3$, or an ample clearance of half an inch on each side. Plate 33 is a longitudinal section of the engine, and its extreme length from steam pipe flanch to fore end of engine frame is 23 feet 6 inches, its extreme width over the main gudgeons being 8 feet 3 inches only; and be it observed, this length includes an extended head stock framing, which (with all respect be it spoken,) I cannot conceive necessary, at least to so great an extent; but there it is, and as I wish to adhere to facts, what have we?—The Hydra's beam engine of 160 horses, requiring 23 feet 6 inches in length, and 8 feet 3 inches in breadth; the Gorgon engine of 160 horses, requiring 20 feet 6 inches in length, and 7 feet 10 inches in breadth—a saving of 3 feet on 23 feet 6 inches, or about one-eighth! I must call on Mr. Pole to show how this agrees with the first item of the Gorgon advantage, as quoted by himself from the pamphlet, viz. that the saving in space is very nearly one-half.

It may be said such an engine has not been made, and is merely hypothetical. I apprehend one thing only is necessary to produce it—an order.* And here I beg to maintain, the question is between the beam and Gorgon engine, and we have not only to prove what has been done, but what can be done, on the principle of the former. Let us take the Medea, by Maudslay. I refer your readers to Tredgold, plates 37 and 38. The former is a plan of the engines of the Phoenix (same as the Medea); the distance between the main levers is 5 feet 10 inches. Here we require a lateral extension to 6 feet 4 inches, as in the Hydra, to make room for a cylinder of 67 inches. This done, the Medea's engine is 7 feet 9 inches over all at the main, or one inch less than the Gorgon! Plate 38 is a longitudinal view of the same; the length of the engine is, as it regards space occupied, only 19 feet, but as in the Hydra, I'll take in the additional piece of frame, and call it 21 feet 6 inches, and what have we?—Medea beam engine, requiring 21 feet 6 inches in length, and 7 feet 9 inches in breadth; the Gorgon engine, requiring 20 feet 6 inches in length, and 7 feet 10 inches in breadth—a saving by the latter of $\frac{1}{4}$ part in length, and an increase in breadth of one inch. Sir, let your readers examine and judge for themselves.

Having, I hope, shown that what may be called engines of some standing can be increased to 320 horses without additional space, I now fulfil my promise, to explain that engines having the same stroke as the Gorgon, viz. 5 feet 6 inches, may be made under these restrictions. In fact, I shall do no more than prove the correctness of Vulcan's "sketch." And here, Sir, I have recourse to the useful table published in your April number, viz. the proportions used by Maudslay, Son, and Field. You state their 100 horse 5-foot stroke is 14 feet 2½ inches from centre of cylinder to centre of crank (see table, the 42nd and 43rd line). Having 6 inches more stroke, say 5 feet 6 inches, we will take this proportion, and find the same distance to be 15 feet 6 inches as near as may be. By Mr. Watt's formula a stroke of 5 feet 6 inches should make 20·186 strokes, or say 22½ feet per minute, to produce a power of 160 horses. At this speed we require a cylinder of 66 inches, the same as in the Gorgon: then for a beam engine on these proportions, we have—

Distance from crank to centre of cylinder	15	6
Half diam. of cylinder, plus flanges, joints, &c.	33	+ 9 = 8 6
Half projection of headstock: in this we take Messrs. Seawards' own practice, as in the Mægara, taking proportion as length of crank, the true guide. The Mægara's stroke is 4 feet 3 inches; width of headstock 4 feet 3 inches. (See Tredgold, plate 49.) In this case the stroke is 5 feet 6 inches: take 5 feet 6 inches ÷ 2 =	2	9

For the whole length of the engine	21	9
------------------------------------	----	---

The width of such an engine would be as that of the Hydra, viz. 8 feet 3 inches. Thus, what have we here?—A beam engine, as the Gorgon, 21 feet 9 inches in length and 8 feet 3 inches in breadth; Gorgon engine 20 feet 6 inches in length, and 7 feet 10 inches in breadth—a saving of 15 inches upon 21 feet 9 inches, or just one-seventeenth part, and in breadth a saving of 5 inches upon 8 feet 3 inches, or about one-nineteenth part. Does not this call for explanation?

* Since writing this, I have been credibly informed that a pair of beam engines of this power, or nearly so, are constructing by Boulton and Watt.

tion? I have not done yet, but fear being prolix, although I hope you will bear with me, as it is of great importance to the profession that this matter should be set straight.

Let your readers consult Tredgold, plate 49, being a longitudinal section of the Mægara's engines. They are stated to be seventy horses, having a 44-inch cylinder, and 4 feet 3 inches stroke; according to Mr. Watt, this should travel 206 feet per minute, giving a power of 66 horses. Now this engine occupies 17 feet 6 inches in length for this small power; and if the Gorgon engine is compared with such beam engines, perhaps a better case might be made; but that, I humbly submit, is not the point in dispute.

Having given your readers comparisons of Boulton and Watt's and Maudslays' practice, let us go north, and show what our Scotch friends can do. Let them look at Tredgold, p. 41—a section of the Don Juan's engines, by Claud, Girdwood and Co. (I am now speaking of space only). This is an engine of 6 feet stroke, and 68-inch cylinder, at 7 lb. equal to a power of 176 horses $\times 2 = 352$ horses, or 32 more than Gorgon; and what have we here?—

A Clyde beam engine, over all	23	3
Gorgon engine	20	6

—A saving of 2 feet 9 inches upon 23 feet 3 inches, or about one-eighth. No plan of this engine is given, so I cannot compare as it regards lateral space, be it observed this scheme is like Vulcan's sketch, particularly in the way the longitudinal pressure of the shaft is resisted by large deck beams; and is there any reason why this should not answer in a beam as well as in a Gorgon engine? Should it not even be better from the greater length of the connecting rod?

In concluding the subject of space, I will draw attention to the facts that I have shown:—

1. That the Hydra's and Medea's engines may be increased to 320 horses, without material additional space.
2. That a beam engine of the Gorgon's proportions may be constructed as sketched by Vulcan.
3. That the Don Juan's engines are 32 horses larger than the Gorgon's, and only 23 feet 3 inches long.
4. That the saving in No. 1 is about one-twelfth, in No. 2 one-seventeenth, and in No. 3 about one-eighth, this latter being of larger power.

Mr. Pole assumes an argument in favour of the Gorgon engine, upon the number made by the Messrs. Seaward. Let me repeat Vulcan's assertion, that with two foreign exceptions, the "British Government is the only patron of the Gorgon engine." No commercial man connected with steam navigation will look at them.

I do not think Vulcan political in reflecting on the judgment of navy engineers: they are notoriously behind, and have great lee way to gain. Mr. Pole will recollect that, not long ago, we had a highly favourable report on Hall's condensers; that thousands were expended on Morgan's wheels; still the first invention did not extend beyond the Mægara, the latter is now exploded; may we not suppose a similar fate awaits the Gorgon engine? I think Vulcan's prophecy most reasonable and probable. It may be said, the Government are the persons to make experiments. True; but should they not be guided by discrimination and judgment in the selection of subjects?

But other firms are making "direct engines." Government say "We will have no other: what are they to do? They must comply, or lose royal favour, shut up their shops, or find work for their people. Is the course difficult to decide? 'Tis what is vulgarly called "Hobson's choice." But if we are to have "direct engines," let us have them in a shape that offers compensation for their acknowledged disadvantage. If credit is to be given to the Messrs. Seaward for a reduction of one-eighth, or one-twelfth, or one-seventeenth, what amount of admiration is due to Maudslay, to Boulton and Watt, who, in the Devastation and Virago, have annihilated space to one-half that of the Gorgon engine! Could those gentlemen have stooped to such species of advertisement, with what propriety could they have published a pamphlet, and with all the "pomp and circumstance" of success, have said—1st. "A great saving (nearly one-half) of the space usually occupied by the engine in the vessel."

I now advert to the important subject of the weight of marine engines. Vulcan states "the assumed weight of the Gorgon's machinery was 257 tons, and that it really weighed 298½ tons." This has not been contradicted, and I presume it to be correct, as great care was taken; Government appointed a special officer to see each portion weighed. Now I am fully aware of the difficulty in assuming weights of machinery, especially that of a new design, and do not think much of the Surveyor of the Navy's annoyance at finding some 40 tons more on board than he had displacement for; but that is not the point of difference. It is, what proportion does this 298½ tons bear to the weight of a pair of beam engines of 320 horse power?

Much has been lately said concerning the great weight, bad proportions, and large consumption of coal, of the Clyde engines; with what truth, it is not now my intention to inquire, but their makers can bear it well, when they recollect, before they became of sufficient importance to be considered as rivals, that the same charge was brought against Boulton and Watt. Mr. Pole, supposing Vulcan to be of "Bromielaw" origin, gives them a very sly hit. He says "Four pairs of 280 horse power, made in Scotland, exceeded the assumed weight by 60 tons each pair." If so, it only proves that they (the Scotch) aimed in a greater degree than the Canal Iron Works, in the exact proportion of 280 to 60, as 320 is to 40, nothing more. Are we to qualify our own errors, by exaggerating those of others? No, no, the Gorgon engine is a Thames production: let us try it by its *compeers*. Here I must accuse Mr. Pole of a quibble. He throws aside all the machinery but the *ENGINE*, as I observed before; as it regarded *space*, this is a perfectly fair comparison, but not so as it regards the weight. He has shown the engine alone to have exceeded its estimate by two tons only. True; but engines are scarcely complete without paddle-wheels. To avoid any misunderstanding as to the shafts and other portions being put to debit or credit, let us take them both together, and we have—weight given, 145 tons; real weight 163; a difference of 18 tons. Here lies the quibble: it must be evident, even to the unprofessional reader, that a saving in one portion of a ship's machinery, if counteracted by increased weight in another, is of small use in result, and that in comparisons of this sort, it is proper only to take the *total weight complete*. This I do! Vulcan states the Gorgon's weight to be 298½ tons, and he has not been *directly* contradicted. In the table, p. 133, Mr. Pole puts it at 280 tons. Had we not better call upon Vulcan to produce his promised "official" report upon this subject? Appropos of this very admission, that the Gorgon engine is 0·88 of a nominal horse per ton, and that beam engines are about 1·00 ton per horse per hour; the difference here is just 0·12, or less than one-eighth, and the pamphlet, see art. 2, promises a saving of 25 per cent., or one-fourth. May not the Messrs. Seaward say, "Save us from our friends?"

This last statement of Mr. Pole is in accordance with my own practice. I have now before me a list of 52 pairs of beam engines, made by an eminent firm, averaging from 300 down to 40 horses collectively. The smaller power, say to 2, 60 horse, certainly are not more than ·9 of a ton per horse, not being encumbered with coal boxes, a rather formidable affair in very large vessels. The larger powers generally having this additional weight average one ton per horse: in one or two cases this was exceeded, in others not reached, depending on the *depth* of the vessel, and other data not necessary to be enumerated. And these weights include engines, paddle-wheels, boiler and apparatus, coal boxes, water, duplicates, and tools, &c.—in fact, complete for service.

Mr. Pole states the weight of the Monarch's engines (the Nile's were exactly similar,) at 270 tons. I take this for granted, as I am not able to obtain any corroboration. Now I have already shown, by reference to Tredgold, that these engines may be increased to 320 horses, without increase in space, and by the substitution of a single cylinder 67 inches in diameter for a double or jacketed one 55½ inches in diameter, without any material increase in weight. Taking a beam engine at one ton per horse, we have, 320 tons—270=50 tons surplus, to be expended in strengthening the working parts if necessary, and in increasing the boiler to the required power. I have shown the Medea may be increased to 320 in like manner. Her weight is 240 tons, and 320—240=80 tons surplus for purposes above stated. I have no hesitation in saying it is very ample, and that an engine 5 ft. 6 in. stroke, as sketched by Vulcan, could be constructed to weigh no more than 300 tons.*

The last item is the consumption of fuel. I admire Mr. Pole's wit more than his judgment, in bringing a heavy charge against Vulcan—that of "gratuitous fabrication." He should have been careful of his facts here, as it vitiates a somewhat well-written paper. Vulcan not only speaks of the pamphlet, but also "some of the published statements and assumed facts;" see his second paragraph, certainly a very temperate one. If it can be shown that the Messrs. Seaward *have published the fact, that their engines require 6½ lb. only per horse per hour*, I apprehend Vulcan's error in having quoted it from the pamphlet instead of from other papers, will be considered venial. This I will do.

I have now before me, (and they are sent for your inspection) five publications, hand-bills, call them what you will, the three first extolling "Mr. Samuel Seaward's patent expansion slide valves and salt detector," the fourth a lithograph copy of letters from the commander

and engineer of the Gorgon, detailing her wonderful and unequalled performances on the north coast of Spain, and the last is a sort of compendium of the foregoing, as well as a species of "olla podrida" of the productions of the Canal Iron Works. It is an extensive affair, epistolary in its form, and therefore certainly *not* intended for private circulation, so that I commit no breach of good manners in bringing it before you.

In this last production it is worthy of note, that the claim of "saving in weight" is reduced from one-fourth to one-fifth—an improvement in the right direction, most surely. And the 4th article says "a great saving in the consumption of fuel"; and, further on, (I copy the whole paragraph,) "we guarantee that the consumption of fuel in our marine engines, constructed upon our improved system (that is, the Gorgon engines, for nothing else is hinted at,) shall be UNDER SIX POUNDS of good coal per horse per hour, the engines working at their full efficient force, with the steam passage open at least four-fifth of the entire stroke of the piston."

Mr. Pole takes a common-sense view of the question, when observing there is nothing in the "direct system" alone which could produce a saving in coals. But the claim of *under six pounds* is staggering in any kind of engine, and being placed alongside other matter of an apocryphal nature, demands notice. If the saving is not in the engine, it may be in the boiler, or probably in the felt or jacketing. Let us give credit where it is due.

If there is any irrelevancy in the introduction of this "fuel question," it cannot be ascribed to Vulcan, but to the proprietors of the Canal Iron Works, who, in vinding their Gorgon engine, have claimed for it properties which it does not possess. Is the saving in the boiler? Has it, from its scientific proportions and construction, greater evaporating powers than those of other manufacturers? To this I answer, no, so far as my experience and practice will allow me to discover. I do not say they are copied therefrom, but they have the same arrangement of flue as those made by Maudslay some years previously or the Dee, Messenger, Phoenix, Salamander, &c., and I should say were capable of evaporating at atmospheric pressure about 15 cubic feet of water with a cwt. of good coal, that is, about 8½ lb. of water with a pound of coal. The grate surface is small, being 165·6 square feet, a little more than half a foot per horse, say 0·52, and I make the total surface (not taking the *bottoms* of flues) to be about 3388 square feet, or 10·6 per horse.

Your professional readers will see nothing very new in all this; and if the facts are disputed, I am prepared to send you authenticated drawings, not only of the boilers of the Gorgon, but those of the Dee and Messenger, that they and you may draw their own inferences. The clothing only remains. I do not know of any experimental knowledge on this head on which we can rely, to show the ratio of saving by its adoption, but hope at a future time to lay such before you.

The Messrs. Seaward, in the aforesaid "olla podrida," say "The great saving we are enabled to make in the consumption of fuel we accomplish in part by OUR NEW MODE of clothing or jacketing the boilers, cylinders, &c." "OUR new mode"! What is it, and in what does it differ from that which has been adopted by other engineers for years before the Seawardian era? Surely all credit on this head is due to "Watt," who was, of all others, the most forward in recommending this plan. True, he used sawdust, and found it to answer excellently as a non-conductor. I am old enough to remember that, so far back as 1817, felting the boiler was adopted. Some of your readers probably recollect seeing in the autumn of that year a small vessel called the "Caledonia," which was purchased by the *present* Mr. Watt, and in which he placed a pair of 14 horse engines, and subsequently ascended the Rhine as far as Coblenz, to show the natives what steam could do. The boiler of this vessel was *felted*, aye, and carried out to a great extent. The front of it was covered with *black tin*. I cannot tell the amount of saving in coal, but the comfort of the officers and crew was materially increased. It is unnecessary to follow this subject further, to show the antiquity of the practice of "clothing." I therefore humbly submit that the words "our new mode" should be expunged from this advertisement, or that the Messrs. Seaward explain unto us on what grounds they put it forth.

I cannot omit to notice that which follows the foregoing quotation. Speaking of the reduced consumption, they say we are enabled "more particularly to accomplish this by a most valuable improvement, for which we have letters patent," that is, "causing the spent steam from the cylinder, before it enters the condenser, to pass through and give out its heat to the feed water." This I conceive to be as scientific an improvement as could well be devised, and give the Messrs. Seaward great credit for the same.

But taking all the claimed novelties and improvements detailed in the five publications, together with those in the pamphlet, I cannot see any reason to conclude that they would produce so low a con-

* Would Mr. Alexander Gordon favour us with the weight of the Don Juan's engines?

sumption as *under six pounds*. The onus lies with the Messrs. Seaward, to prove this upon scientific and practical data; and until they do so, I must conclude, with Vulcan, that they have been carried away by enthusiasm.

The following data and dimensions on which the Gorgon was constructed, may be relied on:—

	DIMENSIONS.	ft.	in.
Length between perpendiculars		178	0
Keel for tonnage		152	3
Moulded breadth		36	4
Extreme ditto		37	6
Depth in hold		23	0
Tonnage		1108.	
	DATA.		
Weight of masts and rigging		25	tons.
Anchors and chain		50	"
1000 men		133	"
Engines and water		27	"
Coals		300	"
Hull		630	"
Provisions and stores		78	"
Total		1486	

Displacement at load line . . . 1412 tons.

Load line 12 tons to an inch immersion.

I give you this, that I may put a few questions to Mr. Pole. He says "the speed of the Gorgon's engines, with 400 tons of coal, is 19 strokes per minute; with 200 tons, 21 strokes per minute." One or the other appears incorrect; thus $420 - 200 = 220$ tons difference. The Gorgon at her load line is 12 tons per inch; we have $\frac{220}{12} = 18\frac{1}{3}$ inches decreased draught, with the 200 tons on board. It would be more than this, for at 18 inches below her load line, she is probably not more than $10\frac{1}{2}$ or 11 tons per inch. But say 18 inches; does Mr. Pole assert that the paddle wheel (26 feet 10 inches working diameter by 7 feet 2 inches long,) relieved of 18 inches dip, would only make a difference of *two strokes* in the engines? Again, with reference to the Styx, he says "she had 260 tons of coal on board, and went 21 strokes." Where did she get them? I allude to experiment, 6th May, 1841 (see, as referred by you, p. 210, vol. iv.), on which occasion she started from the Canal Iron Works; and I believe the Government are not in the habit of sending coals to their ships away from the dockyards, especially so large a quantity as 260 tons. With regard to the speed of the engines, you, Sir, settle that—it was 17 strokes; so we must have these questions answered before we finally convict Vulcan of falsehood.

By the bye, allow me to lecture yourself for two very important errors in the paragraph p. 210, vol. iv. First, you say the Styx's engines are 560 horse power, cylinder 62 inches, 5 feet 3 inches stroke. According to Mr. Watt, this gives 140 horses each engine, or 280 only for both. Secondly, you say the Styx is fitted with Mr. Seaward's *patent* engines. This controversy has already shown there is nothing of the sort. There are other points which I would wish to go into, especially relating to the evaporative power of the boilers, and their incapability of producing steam equal to the supply of cylinders of 66-inch diameter, 5 feet 6 inches stroke, and 20 strokes per minute, at a consumption of "*under six pounds*": but fear I have already transgressed too much on your space; I therefore reserve this for a future communication.

I refer to the statement of Vulcan that one-third of the power is absorbed by the friction of the piston rod, merely to say that I do not understand it. Verily it appears in its present shape to be nonsense, and is either a misprint, or error in expression. Let Vulcan explain; and perhaps in the mean time Mr. Pole will give us *his* version of the subject.

I have heard, and I have read, not only in the *Journal*, but in a talented Glasgow contemporary, "dark and mysterious hints" of collusion between public officers and private establishments. How far this is correct I am not prepared to say, but hope, for the honour of the profession, that it is not true. However, it behoves the principals of all our large establishments to come forward, and remove this aspersion upon their honour. "Competition" is a glorious thing for the advancement of both theoretical and practical science; let us have it to repletion, but *let that competition be fair and honest*. Possessing, I am proud to say, a somewhat extensive acquaintance among the members of the profession, I am sure there is *not one* but would emphatically agree with me in this sentiment; but I am sure they will equally "grieve" with me at the following:—The *Mechanic's Mag.*, (No. 974), has a continuation of the *olla podrida* species of advertisement. It states "the Admiralty have given instructions to build a

large frigate, the *Penelope*, of 650 horse-power—that it is the proposition of Mr. John Edye, and that the commission for building the engines has been given to the inventors of the *Gorgon* plan, the Messrs. Seaward and Co."

Those who know Mr. Edye are well aware that his talents and accomplishments are great and various, and that the natural modesty of his disposition, added to the dignity of his official situation, would not allow him willingly to have his name thus brought forward for others' uses. But has the executive of the Admiralty acted with their usual fairness in this case? They have given unto the Messrs. Seaward this large order to the amount of perhaps £25,000, *without consulting any other establishment*—is this fair or honest? Is it a proper compliment to the profession generally, when it is known that others have improved upon what is termed the *Gorgon* engine even to a moiety, as it regards space. To what are we to ascribe this partiality? is a question I decline to answer.

I am, Sir,

Your's very truly,

PERSEUS.

London, 12th April, 1842.

SIR—I should not again have troubled your readers with any further remarks on "Direct and Beam Action Engines," had not an article appeared in your April number under the signature of Wm. Pole, in which an investigation of the relative amounts of friction in the two descriptions of engines is imperiously and confidently demanded.

I am glad of the opportunity thus afforded me of correcting an ambiguity in one of the sentences upon that subject, which unfortunately escaped my notice until it appeared in print in your January number. It might, indeed, seem that I had wished to convey the impression that the friction on the parallel motion of the Gorgon engine equalled one-third of the power exerted—but far was it from my intention to express so palpable an absurdity: when comparing the amount of friction upon the parallel motion in the beam and direct engine, I might well call it *relatively* enormous in the latter case, "upon those parts the strain on which, caused by the short connecting rod, is so great as to equal one-third of the power of the engine passing through them to compel the piston rod to move in a vertical line"; the uncertainty as to my meaning arising from the accidental omission of the words "the strain on which," I much regret, as it has caused me thus in explanation to trespass on your valuable space, and gave your correspondent an opportunity which, in his desperation, he seized upon with avidity, of proclaiming a transient triumph.

That the lateral strain does amount to one-third of the power exerted is simply shown:

Let a be the angle which the connecting rod makes with the vertical, and let P represent the effective force on the piston; then,

$P \secant a$ = strain along the connecting rod,

$P \tan a$ = the horizontal thrust; and when the connecting rod is three times the length of the crank, the greatest value of $a = 19^\circ 28'$, in which case the lateral thrust equals $P 3534$; this pressure has to be sustained by the parallel motion or guides whichever may be adopted, and in practice causes great wear and tear on those parts, nor has any combination been found effectually to resist the strain for a length of time.

Having already far exceeded the limits between which I had hoped to have confined my remarks, I shall defer, for the present, making any allusion to the subtleties and the assumed knowledge of facts with which Wm. Pole has filled his communication, but shall not fail to do so on an early occasion, unless, indeed, some of your readers, with a readier pen and more time at their disposal than I have, should be roused by indignation to expose the fallacies with which that paper abounds.

Sir, I am,

Yours, obediently,
VULCAN.

London, 19th April.

INLAID MARBLES.—A beautiful mode of ornamenting marbles has recently been brought into use in Paris. It consists in etching, by acids, deeply into the marble, various designs upon a properly prepared bituminous ground. When the corrosion has gone sufficiently deep, the cavities are filled up with hard coloured wax, prepared so as to take a polish equal to that of the marble when cleaned off. Drawings thus made on black marble, and filled in with scarlet wax, after the manner of Etruscan, and certain Egyptian designs, are said to have a very noble effect, and are applied to tables, panelling, stoves, &c.—*Repertory of Patent Inventions*.

ON FRESCO PAINTING.

BY JOSEPH SEVERN, OF ROME.

*(Read before the Royal Institute of British Architects, on Monday, March 14, 1842.**

I CONFESS myself almost an enthusiast on the subject of fresco painting, having had the singular happiness to pass half my life in Italy in the midst of the finest fresco works, and having enjoyed the friendship of all those modern German artists who have revived and perfected this manly and useful style of art, and created a classical city in Germany. I am therefore sanguine as to the great probability of success attending the proposed introduction of this *architectural* style of painting, although new and strange to the English artist, as well as the people; believing that, if successful, it will be the means of introducing and establishing in England the grand style of historical art hitherto unknown here. If this beautiful style of painting be successfully introduced here, it will be more indebted to the helping hand of British architects than of British painters, for it can only be understood and felt by those who have seen with their own eyes the magic of its power in its great Italian examples. Now architects, more than painters, have visited the places where those wonders of fresco art still live triumphant, after the lapse of three and four centuries, defying the ravages of time, and almost of man (the greater destroyer of the two); and in studying the principles of architecture in those classic regions, the English architects have involuntarily taken fresco painting as a branch of their own noble pursuit.

I began by calling Fresco "Architectural Painting," because it is on this ground that its advantages are most evident, and it is on this ground we have to consider it—indeed, strictly speaking, fresco is purely architectural. I will not enter into any details about the material, which has been so much discussed, and is now so well known; but I will endeavour to explain and contrast the theory of the fresco art in its principles and object, as compared with oil-painting—the great difference betwixt the one and the other—and the different ways of acquiring the former.

Oil painting is more applicable to the other purposes of art, particularly moveable art. Its excellence is seen in cabinet pictures of domestic scenes, portraits, and the like. It has force and delicacy in history and landscape, and its finest specimens have deservedly won the admiration of all times; but it is in reference to architecture that we are now to judge it, and I say that fresco painting alone is adapted to this purpose. The shining surface is an insuperable objection to oil, as it requires particular and concealed lights to get the general effect, or rather the whole effect of the picture from every part of the room. Now this, as regards large works, such as national history demands, is impossible, since no construction of building, not intended as a picture gallery, can possibly admit of it. And even in picture galleries, how difficult, how rare it is (although they may be actually built for the purpose) to see the pictures well and entire. I need only mention the National Gallery, where the finest work of Italian art in England, the Sebastiano del Piombo, cannot be seen entire from any part of the room at any hour of the day; and I am sure I need not point out how necessary it is to the true effect and understanding of a large historical work that it should be seen entire at the first glance; and how completely the dodging about to find a spot whence the picture can be well seen, frustrates the aim of the painter. This does not apply to small pictures, which can be well seen anywhere; I am speaking only of large works, such as national works are and must always be. At Venice, three of Titian's most celebrated works are comparatively invisible, for these reasons. My remark applies generally to oil pictures in churches: so much so that in Italy they are beginning to remove the principal works to public galleries, constructed for the sole purpose of exhibiting pictures; thus, as you will at once perceive, destroying the local object of the paintings, either as to their moral or religious purpose, and even the architectural decorations for which those paintings were formed. This is the case with the "Transfiguration," which no doubt would interest us more in the actual place for which it was painted, if it could be seen there; and the same may be said of most of the celebrated altar-pieces. The oil-painted staircase of the British Museum you have all seen, or rather *nobody* has seen, as it never could have been seen, owing to its dazzling glare, even by the painter himself when he did it—but you know enough of these examples for my purpose, which is, to show the immediate connexion of architecture and fresco painting.

* This paper we intended to have published in the last month's Journal, but through want of room we were obliged to postpone it to the present month; it has in the mean time appeared in the "Athenæum."

As regards light, fresco is seen entire in any situation and by any light; even candle-light, which, I think, perhaps shows it best. I remember seeing the Carracci frescos, at Rome, during a ball, when I was struck by their increased beauty and power, owing to the warm light; even a dim or diminished light does not destroy their effect, for fresco pictures are always well seen, with any kind of window, or even without any positive light. It must have been for this reason that Raffaello adopted fresco in the Vatican, after he had made experiments in oil; for the rooms are so ill lighted that oil pictures could never have been seen at all, and it is surprising to find such fine works in such a place. Three sides of the rooms are illuminated merely by the reflected light from the great wall of the Sistine Chapel, yet this beautiful and luminous material of fresco is so brilliant in itself that the pictures are well seen. Nine of them were painted without a ray of real light, and have always been seen in the same way. I think this a very important consideration, for, as we have but a diminished light at any time, it is most necessary to adopt a manner of painting suited to it, which can be seen at all times. Such is the power of fresco, and such, as regards light, makes it preferable to oil for all our purposes.

The fact of Venetian painting, as regards the decorations of architecture, being in oil, I consider to have arisen entirely from the singular locality of that beautiful city. It was soon discovered (as Vasari mentions in the *Life of Giorgione*), that fresco was but a perishable thing exposed to the sirocco and the sea air, for the frescos of Giorgione in a few years were destroyed. This, I have no doubt, led to the adoption of oil-painting there for architectural decoration, as it was found to be more durable. But this argument applies only to Venice, for the other great Italian cities are adorned with fresco; nor can it be urged in favour of oil being employed here, as the localities of London and Venice are wholly different. There are frescos by Titian at Padua well preserved; yet at so short a distance as Venice you find nothing of the kind, save the skeletons of Giorgione's works on the fronts of houses. This may be a reason for not employing fresco in the open air in England, for, as it does not stand well in Italy, it may be presumed that here it will not stand at all.

But the great objection to the employment of fresco in this country is on the ground of colour and effect, for it is generally confounded with scene-painting; that the Cartoons of Raffaello are the same as his frescos; and that the colour and effect of one and the other would never do for English eyes. Now this mistake is extraordinary and unpardonable, for, as fresco is done on the wet plaster, imbibing and incorporating transparent colours, as well as opaque, (something similar to water-colour painting when body colour is used on the lights,) producing a richness of tone, surface, and touch, always equal, and sometimes superior, to oil-colours; so it bears little or no comparison or relation to distemper-painting, which is done on a dry ground, and does not admit of any richness of colour. This will be clearly understood by those who have had the good fortune to see Raffaello's and Guido's frescos at Rome, which, for colour, are exquisitely beautiful, and even powerful in all the fascinations of this part of the art, presenting to us still greater varieties than oil painting can pretend to; excelling in all the delicate effects of atmosphere, from the gorgeous daylight, the air of which you seem to breathe in a fresco picture, down to the silvery fitting charm of twilight. In these particulars it reminds us of English water-colour effects. Then I should mention the magnificence of fresco landscape, and of landscape backgrounds, particularly by Domenichino, in which not only the characters, but the movements of trees are always rendered in a way which I have rarely seen in oil colours. And when we consider the ease with which the effects of atmosphere are produced in fresco, and the difficulty and immense labour of producing the like in oil—when I tell you of the advantages even of the dark grey wet ground in fresco, drying out light, and producing so many beauties of aerial perspective in that actual drying, so much variety and transparency of colour, so much lightness and vivacity, so much of what the Italians call "light within"—the superiority of fresco cannot be doubted on the ground of colouring, as applied to architecture. Who does not remember the splendid colouring of Guido's "Aurora," at Rome?—colour so inimitable that, of hundreds of copies in oils, I have never seen one that gave an idea of the original. What of Titian's or Paul Veronese's is there to equal Raffaello's fresco of the Bolsena miracle, in truth of colours?—or the Heliodorus, was it ever surpassed?

If I have to speak of chiar-oscuro and its wonders, I should refer you to the frescos of Guercino, particularly at Piacenza, where are his finest specimens. The portions of his oil paintings which are black and monotonous, (the effect of time on his dark grounds,) in his frescos are transparent and lucid in the highest degree, with a power of shade which I consider superior

to Rembrandt, inasmuch as it gives an extended light instead of a spot, while the masses of shade form the effects of the pictures. It must be considered that time has not changed the frescos, and that it is only in them we can understand Guercino as the Magician of Painting, which he is called by his contemporaries. Till I saw these Piacenza Frescos, I used to consider him as a "vile shade-hunter." Another great painter in chiar-oscuro, never understood in oils from his blackness, is Spagnoletto, whose works in the church of St. Martino at Naples are amongst the most striking things in art. The same may be said of Raffaello's strong effects. In his oil pictures we see midnight shadows in noon-day, as in the "Transfiguration;" but in his frescos it is all truth and beauty, with power. The "Peter delivered from Prison," and the "Flight of Heliodorus," have the charms of Corregio and Rembrandt. Then I must remind you of the grandeur of colour and effect in Michael Angelo's frescos on the ceiling of the Sistine Chapel. What oil could ever have approached such things? When he said "that oil painting was only fit for women and children," he meant on account of the labour and difficulties of the material, compared with fresco. We are assured he performed this gigantic labour in twenty months, without the usual assistance of colour-grinders or plasterers, but alone with his own hand. There are on this ceiling fourteen figures, of at least forty feet in stature, and nearly five hundred figures, the least of which are double the size of life. While we regard this as the most extraordinary example of individual human power, we must consider that it was only in the simplicity and ease of the fresco material that Michael Angelo could have accomplished such a stupendous work. The preparation of oil colours, varnishes, &c. would alone have occupied the twenty months.

All these works I have cited to prove that the powers of fresco in colour and effect are wholly architectural, and when I remind you of their gigantic proportions, forming and assisting the grandeur of the architecture, I am sure the superiority of fresco must be apparent, as applied to buildings. Oil painting, applied in the same way, even with the advantage of good air and light, is always subject to change to a sickly yellow, like a person sinking into bad health, and losing all his natural colour: but fresco never loses its health and freshness; and if it is to decay at last, like all mortal things, it goes down with its own proper tints—it has a vigorous old age. Another thing I ought to mention is, that so many great artists who have now immortal names, condescended to inferior styles in the Vatican decorations: thus Giovanni da Udine painted the fruit and the flowers, animals, musical instruments, and so on, in a wonderful way; Polidoro did the beautiful chiar-oscuros; and Lucca della Robia executed the coloured tiles for the floors. All those great artists raised the things they undertook under Raffaello, whilst he himself seemed to raise the art when he worked in fresco; for if we consider oil painting up to the period of the Vatican frescos, that art seemed in its infancy. The space, the architecture inspired Raffaello;—in what but fresco could his beautiful mind have expanded?—in what else could he have given us such a range of art, from the most sublime history down to ornaments of fruit, flowers, animals, and even pavements? Has he not given us a world of art in the Vatican? Have not those grand frescos given laws to the art? What is there like the "School of Athens," or the "Heliodorus," the "Parnassus," or the "Burning of Rome"? Such dramatic art had never been seen before, such compositions of figures and backgrounds, such colour and effect. And when it is considered that even the minor details on the ceilings and walls all belong to one grand epic invention on the subject of church empire, I think it must be seen that nothing we have in oil colours has so expanded the limits of painting, and made it the worthy sister of poetry. Can there be a doubt we owe all this to fresco?

I will now consider the great advantage of painting being united to architecture in this country through the medium of fresco; and I trust to show also why oil painting could never do the same, and that we can now only have the long-looked-for era of historical art—art, patronized not only by the State, but by the people at large.

It is impossible to look on the historical fresco painting of Italy, recording, as it does so powerfully, the valour and genius of the Italians, without thinking on England; and reflecting that, with a history more heroic, and with genius more useful, we have nothing of the kind in painting—no public works to remind us of our illustrious ancestors. The Italians adorned their public buildings in fresco, not only with the great events recorded in their national history, but every man recalled and recorded the illustrious deeds of his ancestors, whether public or private, which could confer honour on his name and family. This noble emulation continued from generation to generation; and we see, in the monuments which remain, worthy memorials of the

triumphs of mind in civil arts as well as the triumphs of war. These now, in the fallen state of Italy, are all that remain to her of past glory, and it is this which interests the traveller at every step. Who does not remember the Colonna Palace at Rome?—the family now a name and nothing more, yet its former deeds are written there; the principal of which was the great battle of Lepanto. Hundreds of similar examples might be cited; and the influence of this system of beautiful decoration has extended even down to the cottage, however humble, where you always find some little elegancies to remind you that you are in Italy. It is but reasonable to hope, that when fresco painting shall have been introduced here, under the patronage of the State, it will extend itself in a like manner to the adornment of the houses of the nobility; not only in tracing there the great actions of their ancestors, which may bear comparison with those of any age or country, but in recording the great events of our own times, events which are moving and modifying the world. These are the true decorations of buildings, these are things to be proud of, and these we shall accomplish by the introduction of fresco painting. The oil portraits of our ancestors are all that remain to us, but fresco will portray their actions. When we reflect on the illustrious names, and the illustrious deeds connected with them, there seems no bounds to the field of fresco-painting.

This never could have been accomplished, or even projected, through the medium of oil painting, which, independent of the great cost, required such architectural sacrifices to exhibit it. On the other hand, distemper was too perishable and mean. Fresco will remedy all these evils, for its durability is great, and its expense but small. Then the facility with which it may be cleaned, and the ease with which it may be seen, even at night, are advantages which, I think, must insure its success. The grand Italian hall, decorated with fresco, is unknown here, save in the impossible attempts to imitate it in oil. For myself, I cannot but think that the want of fresco here, when we consider all the advantages of durability, light, cleanliness, and cheapness, must have been the cause why historic art has not risen and kept pace with those magnificent things for which England is celebrated all over the world. The English are a highly imaginative people, in their literature particularly; writers and readers go hand in hand, indulging for ever in the pleasures of the imagination; this extends to every thing, save painting. This limitation must arise from the want of power in the medium, and the consequent want of encouragement; for oil-painting has been too costly for its historical purposes, and, from its rareness, could never rise to sufficient rank to make it worth the while of State or people to assist the education of her artists in that most difficult branch of the art.

The ease and facility of fresco will obviate all this; the education of the painters must and will be improved by it. The necessity for grand composition and manly design, even on a simple cartoon, will, I fully expect, not only improve and raise the English painter till his natural capabilities are fully developed, but will fascinate him on to new and imaginative regions of art. This healthy power in his hands, what will he not do? what are the limits to a style of art, which has all the beauty, clearness, and lightness of water-colour, with the richness of oil, great dimensions and architectural powers? Were it alone for the advantages of design, it would be worth our while, as a school, to introduce it, that we might outface all the railings of the learned and the ignorant, as regards the English school having no fixed principles of design. Indeed, in fresco we shall be able to answer every objection. Who knows but, in the midst of our fresco labours, the public may take us up on this ground of design, and see us through our difficult task of establishing historical art. The active capabilities of the Englishman are universally known; and it is enough that he has the warm support of his countrymen to accomplish anything, however great or difficult. Now, in historical painting he has never yet had this advantage, for the English public has been ever cold and discouraging on almost all occasions of English painters having the misfortune to produce historical works. I am obliged to say misfortune, because I understand large historical pictures are never bought, and never looked at but with feelings of pity. This will be at an end in fresco, for the patronage of the State (we have seen it in all ages, and even now in the various continental states which excel in high art,) is the only means by which a school of history-painting can be formed. The admirable way the State now proposes to do it through the medium of fresco, is the first real chance the English painter has had in his own country, whatever his success may have been elsewhere.

I may take notice here of the great encouragement always given by the English government to sculpture, to the total discouragement and disparagement of painting, which is singular, as in other countries painting has predominated in national art, for it has greater means in its closer imitation of

nature to represent all national acts of war or peace. It has the power of representing men as they are, with their own proper actions and dresses; it has the power of representing everything about them, the air they breathe, and the element in which they distinguish themselves, be it on the earth, or in the water, or the air, or even in the fire; for Englishmen, in that wild, romantic spirit, which distinguishes them from other people, revel and live in all these elements, and, I should say, require the universal power of painting to record their actions, rather than the limited range of sculpture, which always rejects the actual dress, and has no power over the aforesaid elements. The only thing we have in this way, is the little Naval Gallery at Greenwich Hospital; and it is impossible not to be struck with the admirable use and power of this accidental collection, for I believe not any one of those interesting battle pictures was done for the purpose. The old sailors show you round, and describe the subjects in which they themselves were engaged, and at the time you, yourself, become a sailor, for I confess I never knew so much before of our great naval victories as I learned in my visits to this humble gallery. Now what in sculpture will compare with this? what is there that can so come home to us? Will Nelson, at the top of that expensive column, compare with it? certainly not: and yet that meritorious gallery of naval pictures, did not cost so much as the base alone of that proud column. This Greenwich Gallery I take as a golden augury of the success of the proposed national history painting in fresco; for this Sailor Gallery is quite enough to show what fine things Englishmen will do in national painting, when they are working under the patronage of the State and the people, neither of which had they in the pictures I allude to. I do not mean in these remarks to find fault with English sculpture, or grumble at its success; I would not say that it had been encouraged too much, but rather that painting has not been encouraged enough; that other nations make painting and sculpture go hand in hand in the commemoration of national greatness. In France, painting has predominated, in Germany the same, and in Italy always. Here we have had nothing but sculpture, which is singular, as the English are considered to excel more in painting. It may be that the want of fresco has been the cause.

The revival of our Gothic architecture in the new Houses of Parliament must be looked upon as a singularly fortunate circumstance, as regards the formation of a style of fresco painting which shall be our own, both as to subject and the manner of treating it. I mean that this noble style of architecture, replete with beauty and grandeur as it is, and more applicable to all our uses than any other, is *entirely our own*, as it grew up amongst us in the early times, was carried to perfection by us, and, singularly enough, we have still the finest specimens in the world. It belongs to us as Englishmen, and associates with the grandest periods of our history; and we are fortunate in having a British architect, whose genius has caught up the spirit and power, and revived it, as though he had lived in the "olden time." Now this elevated English style, rising into splendour again in the new Parliament Houses, will be the fortunate occasion (and perhaps no occasion could have been so fortunate) of our calling up a style of historical painting in unison with it, that shall be our own, as is the architecture—that shall be bold, manly, and English in all its characteristics, and have beauty and power like the building. Nor do I see such great difficulties in the English school attaining this excellence, as many suppose; for it must be considered, that the British public and the British artists will go hand in hand, mutually assisting each other, both inspired by the English style of architecture, and nerved to revive all the other English arts so closely connected with our national feelings. We shall have fresco painting, wood carving, and stained glass; and we have a wonderful collection of British illuminated MSS, which will form a fine field wherein to hunt for national art, all of which we take up again from the early times of England, when Westminster Hall was built, than which nothing grander, more majestic, or so well suited to fresco painting, exists from one end of Italy to the other. Our former experiments have mostly been in the classic, either Greek or Roman, but always foreign to us, and we never entered deeply into them. We are not a classic people; our tendency nationally is to the romantic histories and customs of the middle ages. We are essentially English in this, our literature tends to it, and is first-rate withal; our finest architecture the same, and still first-rate: then why, if we are now to form a style of national painting, should it not be the same, and with the same bright hopes? Who can visit that magnificent hall of Westminster without thinking on the illustrious deeds of Englishmen? and who that forms these pictures in his mind forms them classically?—I mean with the semblances of Apollos, Adonises, and the like, after the fashion of our neighbours the French. No, in this place we only think of *Men*—of a hardy race of warriors, legislators, philosophers, all working-day men, who never

even dreamed of such things as modern art produces. The tame creations of French academies, or the fashionable ones formed from English theatres, are things to shut our eyes at, that we may open them to behold a race of *men* who sturdily gave England the groundwork of her greatness, before academies or theatricals were thought of. Fashion may possibly lend a grace to many things, but certainly never to historical painting.

The greatest charm of historical painting is, to transport us to the time and place it attempts to represent; our architecture does this, and our painting must do it, or the English people will never be satisfied. In other countries art was made great in this way, for Raffaello, although called classical, is essentially Christian, and associates in his frescos with the period of our architecture. Roman soldiers he puts in the Gothic armour of the Swiss guards, and the same feeling of his time is apparent throughout his works; even his Madonnas are Gothic; yet he took everything he could find to his purpose in the antique, though he never ceased to produce what we may really call Christian art, which was his own feeling. Here is an example for us. But perhaps a better one may be found in our own times in Germany, where, in the revival of the fresco art, the artists have boldly dared to create a style independent of the antique; and, in treating subjects of the middle ages, have produced a style of design, not so classically correct as the Italian, but so adapted to the subjects of those times, so manly and vigorous, with their Gothic heroes so completely called up, that I doubt whether anything more original in art has ever been done. Now it is in this, and not in the mere fresco material, that we should do well to study them. We could borrow some of their magnificent cartoons, which, though done in simple charcoal, are wonderful productions of art, and would astonish us here; for the means are almost nothing, yet the result everything. A studied German cartoon is replete with invention, composition, design, and character, and all this in charcoal alone. It is impossible to imagine the result of such excellent preparations for a picture, or the pleasure to the painter of adding colour and effect—and *such* colour and such effect as an Englishman can add to such preparations. Perhaps I should explain here, that the paper used for this purpose is prepared by a simple wash of very thin glue, which glue, when the charcoal drawing is done, undergoes a steaming from a two or three spouted tea-kettle, with a spirit lamp to keep the water boiling; this easily incorporates the charcoal in the melted glue, and the result is, a solid surface, like a picture. I remember two immense cartoons, which Cornelius executed at Rome in this way, and when done, he cut them into convenient sizes to roll and carry to Germany for the fresco painting. No doubt, the sight of some of these would greatly assist and gratify us; and these we could easily have, for the German artists are as liberal as they are accomplished. As for the fresco material, it is so easy, so simple, and so sure, that I cannot but think we should learn it better by ourselves, rather than pick up the vices of others; for although it may be feared that the first specimens of fresco may appear crude and inharmonious to the English eye, accustomed to the bland, glazing method of oil painting, yet it must be considered, that we are an acknowledged school of colourists, and in so high a degree that it might be cited as the only genuine remnant of fine art in the world in these deploring times; and this alone ought to give singular advantages to English fresco painting. Here may also be considered the height to which the English purification of colours is carried, in their chemical nature as well as their principles in art. This alone, I anticipate, will revive some of the splendours of Italian fresco colouring, in which the Germans have not yet succeeded, and no doubt for this reason. These advantages, joined to well-studied English cartoons, and subjects from our noble history, seem to me a Paradise of Art—a thing to enchant the whole race of English artists, whether in regard to animals, figures, landscapes, flowers, sea-pieces, or even ornamental painting. The facility with which they will exercise their new art, compared with the labour of oil painting, I am sure must win them to think more kindly of fresco when they understand it.

In one point I am confident that they will be brilliantly successful, I mean in the varied effects of aerial perspective; for as this is a part so laborious and difficult in oil, and in which the continental artists never succeed, except when they paint fresco; so I am certain the English artists in this point will surpass themselves, for in the process of the fresco drying, in the change from the wet plaster to the dry, so many beautiful effects come out, that I look forward to the English carrying it further than they have carried water-colour painting, which is acknowledged to be most perfect, and is entirely of English origin.

As regards the combining of fresco painting with architecture, so as to enable them to unite, and have the same object, no doubt there must be great uniformity and simplicity in the style of composition adopted in the pictures

for as the architecture is made up of uniformity, so must there be in the painting something which exists in common. It is for this reason we find such simplicity in the composition of Raffaello's "School of Athens," and, indeed, in all his frescos. This may also account for the simplicity of early painting generally, which was invariably adapted to the purposes of architecture. The artist, indeed, in forming a composition in fresco for architecture, must be guided by all the architectural forms around him; he is reduced to and forced into the simple style of art, if he wishes to be effective. The finest altar-pieces have all something architectural in their composition which is necessary to harmonize with the columns and the arch which surround the picture. I mention this particularly, as I fear it is a style little known and less practised by painters in this country; yet, I dare say, well enough understood by architects, who, no doubt, remember the nature of the composition in the Italian fresco pictures to which I now allude. This style may be the most difficult part of fresco for us to acquire, for certainly it is that wherein Englishmen are inferior to foreigners. In our compositions generally, judging from our Exhibitions, there is little of breadth or simplicity, except in water-colour drawings, which, singular enough, as I found to resemble fresco in colour and effect, so I think they have some of its simplicity of composition, both in landscapes and figures. In oil, on the contrary, composition is lost in a multitude of parts—in fact, Art is studied rather than Nature.

The Theatre has a greater influence on painting than we are aware of which influence must be baneful in every way, for nothing can be more opposed to the purposes we are speaking of than a theatrical taste. In this sense, it is unfortunate to have a theatre so perfect as ours, for the influence extends to both the artists and the public. This taste, carried into fresco would be hideous, but I am sure architecture alone will correct it. A strong proof of the theatrical taste existing here in painting, is, that the English prefer Retsch's designs from Faust, to those of Cornelius, or, indeed, any other German works. Now, the slightest glance of an eye practised in historical works, would find that Retsch's designs are entirely made up in the theatrical taste, and it is on this account they have been preferred by the English, and published here in numerous editions, whilst in Germany they are thought worthless. The grand designs of Cornelius, from the Faust, are not known here at all. So here is a difficulty we really have to get over. There will be much to unlearn on the part of the public, and much to forego on the part of the artists.

In the introduction of historical painting in fresco, the difficulty I hear everybody speaking of, is "How are the artists to learn?" Now it seems, in my opinion, the difficulty is, *how are they to UNLEARN*; for the going forward in historical fresco must be by going back—and back to the fine old and powerful styles, as we have done in architecture, and in getting sure possession, once more, of the strongholds of Art, which we have lost in the search after novelty. In the desire to be new, we have merely taken what other men have left. We must return back to the fine solid Art, as Reynolds did, and add to his labours correct and manly design. Nothing complete or individual (I hate the abused word original) can be attained, if the artist be not well and thoroughly acquainted with all that has been done in his art; if he has not seen with his own eyes—aye, and open, too—the whole range of that art which he professes, as Reynolds did; otherwise he blindly and ignorantly stumbles on some common-place, which has been done better by a hundred others, and which he might have avoided had he allowed himself to know it. I say allowed himself, for the prejudices of painters are proverbial, and are easy to be seen in an Exhibition, where so many aim at a chimney-corner kind of art, if I may so express it; for it is local and limited, and made up of servile imitation, without imagination; and painting without imagination is not Art. Of course I allude solely to historical painting. This can never do in fresco painting, but will, in the artist's new life, hang like a millstone about his neck.

Raffaello, when he began his frescos in the Vatican, looked about him, and embraced and made his own everything that could help him; we see in his works figures and groups from the Roman antiquities, from Giotto and Massaccio, and he even sent young men to Athens to draw the marbles of Phidias, for his object was, to advance the art, rather than himself.

These remarks apply to the introduction of fresco-painting in this country; for it is so different in all its objects, in all its means, that few can imagine it existing on that slender thread of life which painting now finds here. What are the combined powers of a modern exhibition to the purpose? what, but each artist trying the powers of others, instead of his own; diverging annually from his own proper feeling in that rage for novelty and fashion which characterizes the age? and what is the result of these annual thousands of exhibition works, but a positive *drum-drinking at the eye*? Such must never

be the groundwork of fresco, or its failure is certain; and such, I am sure, it will not be, for every artist will be gratified to have his work remain in the place he painted it for, with the same light and the same object,—things he can never have, or even think of, in an exhibition.

The immovability of fresco may, I think, be considered as an advantage. In Italy, certainly, where it exists as part of the building, it defied the French rapacity, for, by Napoleon's orders, every oil picture was removed to satisfy Parisian vanity. It was in vain that many Italian cities endeavoured to ransom the immortal works of their countrymen: the French took the ransom, and then the pictures. But the frescos remain to uphold Italian greatness; they could not be removed without utter destruction, so that the greatest works of M. Angelo, of Raffaello, of Domenichino, Guercino, of Guido, and the Caracci, stood, and still stand untouched, whilst the oil pictures which went to Paris were mostly injured by the French artists pretending to restore them. The "Transfiguration" of Raffaello alone will prove this fact: it has that glaring French colour, chrome, on many of the lights; and, indeed, when the present state of the picture is compared with old copies, particularly the mosaic in St. Peter's, it seems to have lost, in French hands, all harmony of colour, all union of light and shade. Now a fresco has no fear of picture cleaning, for the dirt may be easily removed with simple water. Very lately, the Vatican frescos were admirably cleaned with crumb of bread.

As regards the durability of fresco in this climate, I should certainly be in its favour; for I have observed that fresco is more destroyed by a dampness arising from the foundation of the building, and in the soil, than from any effect of the atmosphere. Indeed, I cannot think the serious decay of the frescos of M. Angelo, Raffaello, and others, at Rome, is satisfactorily accounted for at present. We are told the smoke of the candles, in the Sistine Chapel, has destroyed the "Last Judgment," and that the sack of Rome by the Constable Bourbon, was the cause of the early destruction of Raffaello's frescos in the Vatican, because the German troops made fires in the rooms. Now these assertions fall to the ground, when it is considered that recently the Pauline Chapel (in which was performed the ceremony of watching the Host with some thousands of candles,) was cleaned, and M. Angelo's frescos (before invisible from soot) came out quite as well as those in the Sistine Chapel, where the candles are comparatively but few. This is a proof that the smoke is not the cause of the decay. As regards Raffaello's frescos, I have a proof that fire itself does not destroy the fresco material; so that, in this dilemma, I venture to trace the cause of this singular dilapidation of the finest Roman frescos to the *dampness of the soil of Rome*, which is beyond what I have observed in other places. As I passed sixteen summers there, I can judge of its pernicious effects, and have no doubt that it attacks the foundations of the buildings, and must in this way cause the decay. The Vatican is unhealthy on this account in the summer, and one cannot sleep there with impunity. This dampness is found not only in the plains, but the hills of Rome, though not equally; and even at St. Gregorio, on the Celian Hill, the more recent frescos of Guido and Domenichino are decaying. In explaining and accounting for this painful fact, I beg to remark, further, in confirmation of my opinion, that the decay seems more particularly striking in the inner walls, where there is little or no ventilation, whilst the outer walls are comparatively well preserved, as are also the ceilings. This decay in fresco pictures seems confined to Rome, for at Sienna they are admirably preserved. The same at Florence, where, even in the open air, Andrea del Sarto's frescos are in good preservation. Sienna and Florence are dry in their soils, and hence the fact. The modern frescos at Munich also stand well, although the climate is worse than ours; but the soil is gravel, and so they are likely to be well preserved, even in the open air. The soil of London is well adapted to fresco, both as to its nature, as well as the excellent drainage, for our buildings have the singular advantage of dry foundations. *We have habitable rooms under ground always dry*, a thing not to be found in any part of Italy, where even the ground floor, which answers to our parlours, is scarcely habitable. The floors under ground are always cellars, and have to be entered with great caution, on account of the damp. No doubt the ancient Romans must have had a system of drainage similar to ours, to have made their city so different from the present, as regards health. I believe most of the old specimens of our early frescos are in good preservation, considering the way they have been treated—first with disdain, and then with whitewash.

As applicable to England, I would also say, that the durability of fresco against fire is not one of its least advantages. This was proved at Florence, where, after the church of the Carmine was burnt down, and they commenced clearing away the ruins, Massaccio's frescos were found to be entire, and they exist on the same walls to this day; whereas, at Venice, the greatest works

of Titian—his battles of the Republic, painted in oil colours—were all destroyed in the burning of the Senate House.

I have now enumerated many of the advantages which will result from the introduction of fresco painting into England. I have considered, and, I trust, to some extent proved, its claim, as the only style of painting adapted to our architecture, from its light being suited to all times and places—its powers in colour and effect being equal to the powers of water colour and oil painting combined together—its durability, suited to the nature of our soil and climate, and even our customs, including the accidents of fire; and in conclusion I will observe, that the cheapness with which it may be executed—certainly, I should say, one-half the price of oil painting—will confirm and ensure all these singular advantages. I have no doubt, therefore, we shall have English painting extend from one end of the kingdom to the other, as a universal language. In looking on the greatness of fresco, and its positive relation to architecture, I would say that fresco painting is the true sister of architecture, and oil painting only the sister-in-law.

MR. VIGNOLES' LECTURES ON CIVIL ENGINEERING, AT THE LONDON UNIVERSITY COLLEGE.*

SECOND COURSE—LECTURE I.—RAILWAYS.

MR. VIGNOLES commenced by saying, that, in pursuance of the order stated in his introductory lecture, he would proceed to investigate the principles upon which railways should be laid out under varying circumstances. In calculating the power (of whatever description it may be) necessary to overcome the resistance of a load to be moved on any railway or road, it may be divided into two parts—viz. that necessary to overcome gravity, and that required to meet friction. The former is, of course, common to, and equal on, all descriptions of roads deviating from the horizontal line, and is in proportion to the sine of the angle of inclination; the latter is regulated by the degree of perfection of the road, and of the vehicles moved upon it, and includes the resistance of all obstacles to the rolling surface, or periphery of the wheel, in addition to the axle friction due to the load or weight placed upon the carriage. It has been assumed, from experiments and observation, that the average friction upon a railway is 9 lb. per ton, and that this continues the same at all velocities; but there is reason to believe that the latter part of the assumption must be much qualified. The gravity due to the inclination of the plane being added to, or subtracted from, the friction, as the plane rises or falls, the sum, or difference, will give the total amount of power necessary to overcome the resistance of the load. The power necessary to overcome the gravity being expressed by the proportion which the rise of the plane bears to the weight to be raised (say, for example, a ton), is found by dividing 2240, the number of pounds in a ton, by the denominator of the fraction which expresses the inclination of the plane; thus, on a plane rising one foot vertically in a horizontal distance of 1000 feet, the fractional expression is $\frac{1}{1000}$, and the power (retarding or aiding the load), will be the thousandth part of a ton, or 2½ lb. It is evident that, as we arrive at steeper inclinations, this power will at length become equal to that required to overcome the friction; thus, on an inclination of $\frac{1}{250}$, it will be $\frac{2240}{250} = 9$ lb. per ton, and this being subtracted from the friction, on a railway which is commonly taken at that same amount of 9 lb. per ton, it results that no power is required to move a load down such an inclination, or wherever the gravity and friction are equal, and balance each other. The angle that such an inclination makes is called the angle of repose, but will, of course, vary with the friction due to various descriptions of roads and vehicles. On steeper inclines than such, not only is no power wanted, but there is a gravitating power due to the descent of the plane, and so strongly does this act in steep inclinations, that it is necessary to put on the brake, to retard the velocity which it occasions. It is found, however, when a train is allowed to descend a steep plane without retardation, that, owing to the resistance of the air, it will, after acquiring a certain velocity, cease to be further accelerated; many theoretical writers have fallen into error, by supposing it dangerous to allow trains to descend inclinations steeper than the angle of repose without applying the brake. On railways where there are inclined planes of $\frac{1}{250}$, for several miles together, the trains often commence the descent at the rate of upwards of forty miles an hour, and the speed, instead of being accelerated, has been quickly reduced to little more than the thirty miles an hour, or to such uniform velocity that a railway train will acquire on that inclination, varying a little with the weight of carriages, or the length of the train; such being the case, it is evident that lines of railway for locomotive power, can be safely laid out with inclinations of 1 in 100, and even steeper.

It is of the utmost importance, in laying out a line, to consider the power which is proposed to be employed, and the mode of obtaining it; thus, if it be

intended to lay out a horse railway, to carry coal from a colliery to a shipping place, the line should be made always to descend, and so regulated, that the number of full wagons that may be sent down be that number which may be taken back empty. But horse-power being extremely limited, recourse is had to steam, and the locomotive steam-engine has been applied to railway travelling, as being better suited to the purpose than animal power. The power of the locomotive engine may be defined, not so much by horse power, or cylinder power, as by boiler power, or capability of rapidly supplying steam to the cylinders, and still more by adhesive power, or the weight insistent on the driving wheels, so as to have purchase, as it were, to drag the load after it, for the wheels will slide, more or less, and, under some circumstances, will merely turn round on the rails, without progressing. Many lines appear to have been laid out under the impression that the locomotive engines would always have to carry a *maximum* load, and, in accordance with this principle, and to enable them to do so, it was some short time since laid down as an axiom, that no inclinations should exceed $\frac{1}{250}$, and that gradients should be constantly uniform through the whole length of a line. Experience has shown, however, that the practical cost of conveyance of ordinary trains over lines greatly varying in their gradients, does not materially differ, the wear, and tear, and fuel, seldom being increased so much as 10 per cent., and the other expences and contingences being the same, whatever the gradient of the railway, the difference on the whole expence of working and maintenance becomes very small indeed. In laying out a line, then, the traffic must be considered quite as much in the distribution of it as in the totality; for it is evident that, to accommodate the public, the trains ought to go often, and will, therefore, generally be light; and when we consider the great economy in construction, and the little additional expence incurred in the after working, we may conclude that railways may be advantageously laid out with much steeper inclinations than they have in general hitherto been, particularly in the remoter districts, where the railway system has not yet been extended. A powerful engine will draw an immense load on a level, whereas it often has not more than twenty tons to draw—consequently, gravity ceases to become an object; and even should the traffic increase in course of time, it will be better to send frequent and light trains than, in the original construction, to incur heavy cost to graduate the road for heavy trains, which are seldom to be carried. This principle must, of course, be confined within certain limits; thus, lines may be laid out with better gradients, where the traffic is very great, and will justify the expence and inconvenience which might result from an engine having always to go up a steep ascent. Railways in England have cost, on the average, £30,000 per mile, and the first cost of locomotive power does not amount to one-fifteenth of that sum. The interest on the capital is, therefore, very great, while that on the power is small, as is also, comparatively speaking, the daily cost of transit due to the power only. If these proportions were different, the latter being increased, while the larger amount (the interest on the cost of the works) were diminished, the capital sunk in railways might have been reduced fully one-half, with equal satisfaction and benefit to the public, for whose use they were designed, and with greater profit to the shareholders.

LECTURE II. RAILWAYS—LOCOMOTIVE POWER.

In the last lecture it had been stated that the adhesive power of the locomotive engine depended upon the weight borne upon the driving-wheels. The greatest amount of adhesion of iron upon iron, according to the experiments of the eminent engineer, Mr. George Rennie, as published in the *Philosophical Transactions*, appears to be about one-sixth or one-seventh of the weight of the insistent load. In the locomotive engine, where the bearing of the wheels is upon smooth surfaces, the adhesion will, of course, be less; and in weather when rime or mist congeals upon the rails, it is very small indeed, sometimes none at all. But in ordinary states of the rails, and of the atmosphere, one-fifteenth may be taken as an average. The vicissitudes to which this power is subject, will often account for the varying rates of railway travelling, and it is only when the resistance of the load is less than the smallest amount of adhesive power which the state of the weather or the rails will admit, that the time of transit of a train over any given distance can be insured. Now, the usual weight bearing upon the driving-wheels of an ordinary locomotive, for passenger traffic, is about seven tons, or 15,680 lb.; one-fifteenth of this will be 1042 lb., or, in round numbers, say 1000 lb., for the average available adhesive power of such an engine for moving a load, and on the amount of this alone will depend the weight which the locomotive engine can draw after it. The other principal element which must be taken into account in the locomotive engine—viz. the speed—will depend mainly upon the power of the boiler to generate steam with sufficient rapidity. A boiler may have quite sufficient power to move (at a velocity of three miles an hour) a load of which 1000 lb. shall be the representative, but it must be of a far superior description, and far higher powers, to move the same load at a velocity of thirty miles an hour; and this subject does not appear to have been sufficiently considered, though it is of such paramount importance thoroughly to understand the nature of the moving power to be used, before going into the subject of the gradients, or the principles of laying out the line. The amount

* We are indebted for these reports to our cotemporary the "Mining Journal."

of the load, then, which the engine can draw, will depend chiefly on the adhesion, and the velocity will depend on the boiler where the steam is generated, the cylinders being proportioned to each of these two other regulating powers. And not only must the steam be generated to a given pressure to produce that power, but with sufficient rapidity to continue it; and in keeping up a high velocity, it must be, as it were, rammed into the cylinders, so as to produce the greatest possible effect in the least possible time, and this is the reason why high velocities are so very expensive, as the same effect might be produced by one-fourth the quantity of steam, if sufficient time were given to expand it. But there is yet another circumstance that modifies the amount of adhesion—viz. the inclination of the road. It is manifest that, if the road were vertical, the engine could have no adhesion upon the rails; and, therefore, between the perpendicular and horizontal lines, the power must undergo many degrees of variation, quite independent of the atmospheric causes already mentioned. We have no experiments to determine the ratio of that variation, but, reasoning from analogy, it may be assumed to be as the sine of the angle of inclination, or in the same proportion as the resistance arising from gravity, so that practically the diminished amount of adhesion, on any inclined plane, might be found by deducting the resistance of gravity on that plane from the constant of 1000 given above; thus, on an inclination of 1 in 100, the gravity of the engine per ton (or 2240 lb.) will be $\frac{2240}{100} = 22.4$ lb., and that for seven tons will be $22.4 \times 7 = 157$ lb., which, subtracted from 1000, will give 843 lb. = the diminished amount of adhesion, which will be the limit of the power of the engine on that incline, as regards the load, no matter how great the boiler or cylinder power may be. And to find the load which this power will draw, we must take the sum of the resistances arising from gravity and friction for one ton, and the adhesive power divided by this sum will be the amount sought in tons; on an inclined plane of 1 in 100, the calculation will be found thus:—Friction 9 lb. per ton, *plus* gravity as before, $22.4 = 31.4$ lb., and adhesive power 843, divided by $31.4 = 26.7$ tons, which is only one-fourth of what might be drawn on a horizontal line. Hence the advantage of heavier engines, which are daily coming into use, as also the propriety of coupling the wheels of engines for drawing heavier loads up steep inclines, and by this means the whole insistent weight of the engine is rendered effective by adhesion, and the load the engine can draw after it proportionally increased. In calculating the amount of resistance of a load upon a railway, the friction had been assumed to be 9 lb. per ton, rather in deference to general opinion than otherwise; it was probably much higher. It is considered that the friction of the engine and engine gear is 16 lb. to the ton, but that of the lighter carriages less; however, if this number (9 lb.) should be proved incorrect by future experiments, the principle of the calculation will not be altered, and it will only be necessary to substitute the true number instead of 9. The same may be said with regard to the adhesion; it will only be necessary to substitute for 1000 whatever number shall be found on closer investigation to be nearer the truth.

The power generated in the boiler, and applied in the cylinders, now remains to be brought under consideration. This may be stated to be the capability of the boiler to supply steam of high pressure, to enable the piston to perform a given number of strokes per minute, which accordingly will be one of the essential elements in computing the power of the engine; and therefore it is that we are always unwilling to define it by any number of horses' power, since it is clear that the engine which, moving at the rate of 15 miles an hour, would be called a 20-horse engine, would be styled a 40-horse engine when moving at the rate of 30 miles an hour, all other circumstances remaining the same. But it does not follow that, because the number of strokes per minute be increased, that the power available for locomotion be increased also, and in this consists the essential difference between locomotive and stationary engines, for in the former there are circumstances, as before shown, which circumscribe that power, over which the boiler has no control; and, as regards the locomotive engine, a third point must be taken into consideration. It is a well-known theory, that, if a metallic substance be in contact on one side with water, and that heat be applied to the other, that once the body becomes thoroughly warmed, the caloric will be taken up by the water with as much rapidity as it can be supplied to the metal. Now, in the locomotive engine, there is an immense area of heating surface in contact with the water in the boiler, in consequence of the numerous tubes which pass through it from the fire-box to the chimney, and it is on this principle that what is called the steam draft has been introduced, by which means the caloric is rapidly drawn from the fire through these tubes, and as rapidly absorbed by the water with which they are in contact, for the production of steam. It is evident that, in proportion to the rapidity with which the piston moves, and with which the waste steam is injected into the chimney, will the heat be absorbed by the water from the tubes and steam generated, the effect of which is, that the faster the engine goes, the quicker it generates the steam; and this forms another great beauty and peculiarity in the locomotive engine. The principles of calculating the moving power being thus explained, the way has been sufficiently cleared for entering on the subject of the laying out of railways.

LECTURE III.—After recapitulating a few of the leading points which were stated in the last lecture, the Professor called particular attention to the formula whereon he had based the calculations into which he had then entered, and he now exhibited tables and diagrams in further illustration. The adhesive power of 1000 lbs. was assumed as the average of what a locomotive engine will have in all states of the weather, and of the rails; but if the wheels be coupled, or the insistent weight otherwise increased or diminished, the adhesive power (on which depends the load) will be altered in the same proportion, subject also to variation from the state of the weather and the road, and undergoing the stated diminutions from the effects of gravity on all planes which depart from a horizontal line, the velocity of the train depending on the evaporating power of the boiler. But in the stationary system the engine winds (upon a roller, or over a sheave or wheel) a rope supported by pulleys, placed at regular distances along the road, and to which rope the train is attached. Mr. Vignoles stated that the student may refer with confidence for every information on this subject, to Mr. Wood's *Treatise on Railways*, and commented on the extracts he made from that work.

Atmospheric Railway.—There is also another mode of applying the stationary engine to the purposes of locomotion, by producing through an air pump a partial vacuum in a pipe, thus making atmospheric pressure the moving power; and it may be interesting to state, that the scientific men who were appointed by the railway department of the Board of Trade to inquire into the system of the Atmospheric Railway, had fully recognised that principle, and concurred in considering that the experiment contemplated upon the Dublin and Kingstown Railway extension, and recommended by the directors to the proprietors, as applicable for illustrating the principle on a large scale. On the atmospheric railway the diameter of the pipe or tube regulates the load, but the velocity depends almost entirely upon the diameter of the air pump that exhausts the pipe, the rule being that the area of the air pump must be made as many times greater than the area of the pipe, as the velocity of the train is to exceed that of the piston of the air pump. Thus, if the piston of the air pump be supposed to move at a rate of three miles an hour, and it be required to move a train at a velocity of thirty miles an hour, the area of the air pump must be made ten times the area of the pipe; the diameter will, of course, be deduced from that area. Now, it appears that the most economical pressure in the pipe (which is what engineers must chiefly look to,) is about 7 lb. to the square inch, or rather less than half a vacuum; therefore, this may be taken as the constant of the atmospheric pressure; and if we multiply this constant by the area of the travelling piston in inches, we shall obtain the effective pressure upon that piston, which, as it regulates the load, may be said to correspond to the adhesive power in the locomotive engine, but which, unlike that power in the locomotive, will be undiminished on inclined planes. Again, if we divide this power by the friction (which was before taken at 9 lb. to the ton), we shall obtain the number of tons which the piston, acted on by the atmospheric pressure, is capable of propelling. Thus, supposing we have a pipe of $1\frac{1}{4}$ inches diameter, if we multiply the area of this pipe by 7 lb., we shall find the effective pressure equal to 1078 lb., which, divided by the friction, 9 lb., will give about 120 tons—the weight which can be propelled by means of a pipe of that diameter; and if the piston of the air pump move at the rate of three miles an hour, and its area equal to seven times that of the pipe, the load will be moved with a velocity of twenty-one miles an hour, and it may be demonstrated that, on ascending and descending planes, the speed, although increased or diminished at first, will soon become uniform. Of course, upon the diameter of the air pump will depend the power of the engine which is to work it. The calculations in this case will be similar to those for an engine required to work ropes—in the one case it being required to find what is wanted to overcome the resistance and friction from ropes, pulleys, &c., and in the latter to find the power to work the air pump, and exhaust the air from the tube at any required velocity.

Inclined Planes.—The Professor then recurred to the effect of trains descending inclined planes. Mr. Navier (in his work, translated by Mr. McNeill, which he mentioned as a text book on the comparison of different lines of railway) differed somewhat from the propositions he had laid down: it was therein stated, and Professor Barlow concurred in the statement, that an engine and train did not gain any advantage in descending planes steeper than a certain inclination which they have put as the angle of repose. Now, in practice, Mr. Vignoles did not find it so, but, on the contrary, daily experience proved that, as far as inclinations of sixty feet in a mile, the trains may, under almost all circumstances, have the full benefit of gravity in the descent. Professor Barlow has laid down, in several important works, which from their high standing, will have a material influence upon the public mind, that though additional power be required to surmount steep inclinations, yet, so far from gaining a corresponding advantage in the descent, there will result rather an injurious effect from the necessity of applying the brake. Now, it has been already mentioned, and experiments have been repeatedly made by Mr. Wood, Dr. Lardner, and others, showing that, when engines descend long inclined planes, such as those on the Croydon Railway, the application

of the break is seldom necessary, the speed that would be due to the accelerating force of gravity, being reduced by the resistance of the atmosphere, until it settles down to a uniform and safe velocity. It is evident, therefore, that there is a great deal yet to learn on this subject, when we find authority and practice differing so materially. Mr. Vignoles observed, in conclusion, that, as the laying out of the lines of railway ought to be strictly regulated by the power to be used for locomotion, as well as of the load of each train, and the nature of the traffic, it becomes interesting to consider these principles in respect of the extension of the railway system in this and in other countries; for, looking at the enormous outlay hitherto incurred, lines through remote districts would not be undertaken, unless the first cost of railways, and the annual expense of working and maintaining them, were reduced to a minimum.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

Feb. 1.—The President in the Chair.

"A memoir of Captain Huddart." By William Cotton, F.R.S., &c.

This memoir is intended by the author chiefly to supply some additional facts which are omitted in the account which was published by his son soon after the decease of this distinguished man, whose "great powers of mind, indefatigable industry, and high principles, raised him to a most honourable position in the rank of men of science." Joseph Huddart was born at Allonby, in Cumberland, the 11th January, 1740. His father was a shoemaker and farmer, and had also a small interest in a herring fishery. Young Huddart was placed under the tuition of Mr. Wilson, the clergyman of the village, and from his son, who had been at Glasgow, he acquired some knowledge of mathematics and astronomy. He early displayed much ingenuity in the construction of models of vessels and of machinery; and while herding his father's cattle, he was occupied in mathematical reading, drawing, and calculations. His determination to adopt a seafaring life was opposed by his friends; and it was not until he was called upon to take his share of the duties on board the herring-fishing boats, that his father was reconciled to his becoming a sailor. At this period, during the hours of rest after his labours, he was engaged in making nautical observations, and laid the foundation for the chart of St. George's Channel, which was laid down by him, and published by his friend, Mr. Laurie, and still is the best chart of that locality. On the death of his father, in 1762, he took the command of a sloop which was employed in carrying salt herrings to Ireland. He then constructed a brig according to a model of his own, every timber being moulded by his own hands. In this vessel he traded for some years to America; until, in 1771, he was induced by Sir Richard Hotham (who had discovered and appreciated his judgment and knowledge) to leave the brig and engage in the East India mercantile marine. "In this extensive field of usefulness, Huddart evinced the superiority of his talents and his inflexible integrity;" and his example as a commander was generally followed. While in the Indian service his attention was drawn to the defects in the usual manufacture of cordage, and led to the improvements which he afterwards so successfully accomplished. He subsequently took a prominent part in the direction of affairs at the Trinity House, the Ramsgate Harbour Trust, and the London and East India Docks, where the valuable advice given by him was properly appreciated, as it was also by the civil engineer, with whom he was called upon so frequently to co-operate. The memoir then relates many interesting anecdotes of his private life, illustrative of his general scientific acquirements, and of his amiable disposition. It then details, at considerable length, his experiments for the determination of the lines for ships, which, consistent with stability, and what might be required for stowage of cargo, would give the greatest velocity through the water. The author enters fully into the account of Huddart's inventions and improvements in rope machinery, which he raised to such a pitch of perfection. This machinery, which is now transferred to the Royal Dock Yards, has already been before brought under the notice of the Institution by Mr. Cotton and by Messrs. Dempsey and Birch, in communications for which prizes were awarded. The general introduction of chain cables rendered this machinery less useful, but could not take from its original merit; and, in its present position, it will long remain a monument of Captain Huddart's perseverance, mechanical skill, and scientific knowledge.

Remarks.—Sir James South thought that Captain Huddart's scientific attainments as an astronomer had not received their due meed of praise in the memoir; but more especially, that the equatorial instrument, which he was now fortunate enough to have in his possession, should have been alluded to more particularly. That instrument was constructed by Messrs. Luke Howard & Co., of Old-street, from the designs and under the daily superintendence of Huddart. The greatest part of the instrument was put together with his own hands, and the result of this combination of skill and attention was, that, up to the present time, the instrument had been unequalled; in fact, he must be permitted to say, that he considered it perfect. It had been used for all kinds of observations—transit, declination, and equatorial; and, in all, with equal satisfaction to the astronomer. With it Mr.

Herschel had made many of his observations, and always expressed himself in the highest terms of it. It had been examined by most of the eminent constructors of instruments, as well as many civil engineers, who all entertained the same opinion of its perfection; and, after a minute inspection, one constructor observed, "Here is the best system of edge-bars and bracing I ever saw, and my opinion of the instrument is, that it is perfect in every part." Sir James then related several anecdotes of Huddart's habits of observation. On one occasion, being ordered to sail from Madras at a certain time, he delayed his departure, because he observed a sudden fall of nearly three-quarters of an inch in the mercury of the barometer. The result of this disobedience of orders (for which he incurred momentary censure,) was, that his vessel alone of all the convoy escaped destruction.

The President believed that Captain Huddart was the first to mark out the direct course to China, which was so generally followed at present. He was also the first observer who took a transit instrument out there with him, to determine the rate of the chronometer. It was particularly worthy of notice, that the equatorial instrument and the rope machinery, both which had been designed by and executed under the directions of a self-educated man, destitute of the means of acquiring instruction either in astronomy or mechanics, had both been, up to the present time, unequalled either in conception or in the perfection of their execution. Huddart was the constant coadjutor of civil engineers; he assisted the late Mr. Rennie in many of his surveys of harbours, and on those occasions had always the command of the vessel, even if he participated in the actual operations of the survey. Whether Huddart was viewed as a sailor, boldly striking out for himself a new track to his destination; as a ship-builder constructing a vessel in order to avoid the defects which he observed in the ordinary class of ships; as a hydrographer, displaying in his chart of the St. George's Channel those powers of observation and of reasoning which made him an astronomer; as a constructor of the equatorial instrument, which had been so justly commended; or as a mechanic, designing and constructing one of the most beautiful pieces of machinery on record—he appeared equally great. The Institution was much indebted to Mr. Cotton for this Memoir of Captain Huddart, whose name would be always venerated by every member of the profession of civil engineering.

Mr. Thornthwaite must in justice correct a misapprehension relative to the laying machine for the cable; the idea of that machine originated with the Rev. Edmund Cartwright, who had projected more improvements in cotton machinery than any person, except Arkwright. The machine was materially modified by Captain Huddart, and to him must be given all the credit for the perfection of its proportions, and its careful construction, which had enabled a machine weighing 20 tons, and revolving rapidly upon one vertical spindle, to work for a number of years without costing 5*l.* for repairs. The register, which preceded the laying machine several years, was entirely Huddart's invention, and was the origin of his improvements in rope machines.

Feb. 8.—The President in the Chair.

"Description of the Port of London, and of the Works at the London Docks." By Robert Richardson, Grad. Inst. C.E.

In this communication the author examines the state of the Port of London, when the accommodation for landing and bonding foreign produce, was almost entirely limited to a single spot, called the "Legal Quay," which was only about 1,400 feet in length, extending downwards from London Bridge, affording no greater facilities for commerce in the beginning of the nineteenth century than in the year 1660, when this quay was appointed. This state of things continued until the year 1773, when Mr. J. Sharp suggested the formation of floating docks. In the year 1800, the West India Docks were commenced; in the year following the London Docks were projected, and in the year 1805 the East India docks were commenced. For all these undertakings, Mr. Ralph Walker was appointed engineer, having Mr. William Jessop associated with him for the West India Docks. The paper enters fully into the bad state of the navigation of the river, owing to defective management and other causes; gives a table showing the progressive increase of tonnage and number of ships from the beginning to the close of the last century; mentions the various plans of Dodd, Spence, Reveley, and others, for diverting the channel of the river for the formation of more extensive docks, near the Isle of Dogs; and then proceeds to detail minutely the origin and progress of the London Docks, giving the dimensions and mode of construction of the principal works connecting the Eastern Docks with the Thames, which were constructed under the superintendence of Mr. H. R. Palmer, to whom the author has been indebted for much of the information contained in the paper.

The communication is accompanied by fifteen drawings, showing the details of construction of the locks and gates, bridges, quays, embankments, &c.

** Description of the Ponte della Maddelina, over the River Serchio, near Lucca.* By Richard Townshend, Assoc. Inst. C.E.

The bridge described in this communication, is situated about half-way between the town and the baths of Lucca, in the Grand Duchy of Tuscany; it was built by Castracani, in the year 1317, on the site of one which had been constructed by order of the Countess Matilda, early in the twelfth century, and subsequently destroyed; it is believed that a Roman bridge formerly existed on the same spot. The present bridge is of grey limestone of the country. The large arch of 126 ft. 6 in. span, is of a semicircular form,

and springs directly from the rocky bed of the river, without any prepared foundation. The smaller arches are of various spans, 46 ft. 10 in., 33 ft., 28 ft., and 7 ft. 6 in. The style of construction is somewhat similar to that of the Pont-y-prydd, over the Taff, in South Wales. An engraving of the bridge accompanied the paper.

"Description of the Mill, Forge, and Furnaces of a Welsh Iron Work." By Thomas Girdwood Hardie, Assoc. Inst. C. E.

The author commences by describing the general plan of an iron work, consisting of six blast furnaces, four double-fire refineries, and a forge and mill, capable of converting into bar iron the produce of the six blast furnaces. He then enters very fully into certain alterations of the interior shape of the blast furnaces introduced by him at the Blaenavon works, from which have resulted an economy of fuel, regularity of work, and an improved quality of iron. The principal alterations appear to be, making the interior diameter greater above that at the boches, and establishing a proper ratio between the diameter of the boches and that of the charging place, and proportioning both to the height of the furnace. The opinions are supported by calculations of the quantity of blast used in smelting given quantities of ore, and the effect which the form of the furnaces must have in directing the current of the blast through the materials, by which also the point of fusion would be necessarily affected, and the chemical combinations varied. The particulars are then given of the construction of the furnaces at Blaenavon, and the details of the blowing engines, blast mains, regulators, valves, &c., with calculations of the quantity of blast used in the various processes of the manufacture. The construction of the casting houses, with the mode of ventilating by the iron roof, is detailed. The general arrangements of the balance pits, coke yards, mine kilns, and bridge houses, are shown, and the author proceeds to describe the forge and mill, which have 35 puddling furnaces, with hammers, shears, rolls, and heating furnaces in proportion. He then condemns the usual practice of leaving the coupling boxes loose upon the spindles, as liable to break the rolls, shafts, or machinery, and gives the theoretical and practical reasonings for preferring fixed couplings. The communication is illustrated by three drawings, showing all the details of construction of the iron works.

Remarks.—Mr. Lowe believed that there was an incorrectness in the statement of the iron, after being freed from its oxygen by the heat of the furnace, taking up a dose of carbon from the coke, thus becoming a carburet of iron, which is a fusible compound, and as such fell melted into the hearth. On the contrary, he thought that the iron was combined with carbon in the ore, and that there was not any necessity for the medium of the fuel to charge it with carbon.

Dr. Faraday, in reply to "Why the ore required, or why the iron carried away, any of the carbon of the fuel?" stated, that the ore being essentially a carbonate of iron, the first action of heat, either in the mine kilns or in the furnace, was to draw off the carbonic acid and leave an oxide of iron, and then the further action of the fuel (besides sustaining a high temperature,) was to abstract the oxygen of the oxide, and so to reduce the iron to the metallic state, after which a still farther portion of the carbon of the fuel combined with the iron, bringing it into the state of easily fusible or pig-iron. As carbon may be communicated to the iron in two ways, distinct in their nature, either by contact with solid carbon, as in the process of cementation (that by which steel is commonly converted), or from the carbonated gases, either carburetted hydrogen, or carbonic acid, which occupy nearly every part of the air-way of the furnace, it would be desirable to distinguish, as far as may be in any furnace having a particular form or action, what proportion of the whole effect is due to the one mode of carbonization or the other.

Mr. Wallace stated that the ore was a carbonate of iron, or a protoxide of iron and carbonic acid united, and not a carburet of iron (or iron and carbon simply), as was generally believed. In smelting, the carbonic acid was driven off, the simple oxide remaining; the oxygen of which, being carried off by the heat, left the pure iron, which, combining with the carbon of the coke, formed a fusible carburet of iron, or the pig-iron of commerce.

Mr. John Taylor observed that his brother, Mr. Philip Taylor, being sensible of the advantages to be expected from the use of anthracite in smelting iron, made a series of experiments several years ago, from which he derived the opinion that the carbon absorbed by the metal, and which is necessary to produce it in the shape of pig iron, must be presented in a gaseous state to the mass in fusion; and as anthracite did not afford a sufficient supply of coal gas during combustion to produce the proper effect, he proposed to adopt a very ingenious method, by which this gas would have been thrown into the furnace in such proportions as might be found necessary, mixed with the common air employed as the blast. Circumstances interrupted the course of these experiments, or it is possible that the use of anthracite for this important application might have taken place at a much earlier period than it has happened to do.

Feb. 15.—The President in the Chair.

"Description of Chelson Meadow Sluice." By Theodore Budd, Grad. Inst. C. E.

The sluice which is described in this communication was erected from the designs of Mr. Rendel, for the Chelson Marshes in Devonshire, which, being very low, had previously suffered much from floods, but now are entirely relieved. The novelty in the construction consists in hanging each of the doors respectively by two hinged flat bars of iron, of 18 ft. 6 in., and 15 ft.

3 in. in length, and thus, by placing the centre of motion so high above the centre of gravity of the doors, give greater freedom of action than by the modes usually adopted in similar works. The dimensions of all the parts, and the method of construction, are given in great detail, and are illustrated by a drawing.

Remarks.—Mr. Rendel explained that the sluice doors which had been superseded by those described by Mr. Budd, were of the ordinary description, placed side by side. They were frequently hinge-bound and clogged up; which caused the land to be flooded sometimes for three months during the year; the hinges were attached in the usual manner to the frames, close at the head of the doors, and they required a pressure of at least 6 inches of water to act upon them either way. He considered the principal advantages of these doors to consist in the freedom of action given by the length of the bar hinges by which they were suspended, their giving the full extent of opening, and the pressure of one inch head of water sufficing either to open or close them.

Mr. Prior inquired whether there was any similarity between these sluice-doors and that erected by the President near Blackfriars Bridge, at the bottom of Fleet Ditch. That door was so well hung as to be even acted upon by the wind; and the slightest pressure of water sufficed to open or to close it.

The President explained that the principle was not the same; at the Fleet Ditch sluice double hinges were used, or rather hinges with a link between the part attached to the frame, and that which was screwed to the door;—that form of hinge always acted freely, and allowed the doors to open with a slight pressure.

"On the mode practised in India for obtaining solid Foundations for Bridges, &c., in sandy soils, by means of Wells." By Captain Goodwyn, B. E., Assoc. Inst. C. E.

Piling for the foundation of buildings appears to be entirely unknown in Hindostan; the ordinary mode for securing a foundation, where the substratum is tenacious and rests upon loose sand, is to dig a well until water is reached; a curb of timber is then placed, and upon it a cylinder of brick, 7½ feet exterior, and 3½ feet interior diameter, is built to the height of 3 or 4 feet above the ground. As soon as the masonry has hardened sufficiently, the well-sinker fixes a plumb-line to the top of the cylinder as a guide, and descends within, carrying an instrument called a "Phaora, or Mamost," somewhat similar in shape to a hoe; with this he excavates the earth until the water is too deep; he then commences the use of the "Jham," which resembles the "Phaora" in shape, but is about 36 inches long and 27 inches wide, and is suspended to a cord passing over a pulley above the cylinder. Upon this instrument the well-sinker descends, and diving into the water excavates with the "Jham" the soft earth under the sides of the curb, and is at intervals drawn up with the instrument. The cylinder descends gradually from 6 inches to 2½ feet per day, as the earth is withdrawn from beneath it, and relays of workmen keep it constantly going, lest the sand should settle around it, and cause it to hang up. The natives are very expert in this operation, and not unfrequently remain under water more than a minute at a time. The cylinders have been sunk as deep as 40 feet; but with extreme labour.

A series of these wells being sunk at intervals of 1 foot between them, they are filled with a grouting of lime and rubble-stone, and separately arched over; arches are then thrown transversely from the centre of each parallel pair, and another set of arches turned over the adjacent wells longitudinally; the whole is then covered with masonry, and the pier or other building raised upon it: such foundations are found to answer perfectly in situations where almost any other kind would be washed away.

The communication was accompanied by a drawing of the process, and of the tools used, showing also the modification of the system proposed by Colonel Colvin, of the Bengal engineers, for obtaining foundations for a curtain, or line of wall, by sinking square masses of brickwork, with two or more wells in each, through which the workmen could excavate the soil.

In answer to questions from the President, Captain Goodwyn observed that the greatest peculiarity of this system was that the sinker worked under water; such had been their custom for ages. Upon this kind of foundation, many of the large fortresses in India were constructed, and they stood remarkably well; whereas, if timber piles had been used, the white ant would have destroyed them in a short time.

Lieutenant Sale observed that another main reason for not using piles was, that timber was scarce and dear, whereas labour was plentiful and cheap. Hence the general use of the brick cylinders.

Mr. Parkes conceived the most ingenious parts of the proceeding to be, the sinking through the water, and thus avoiding the risk of bringing up large quantities of sand, and the combination of arches, for distributing the weight of the superstructure equally among the brick shafts. Such shafts had been used by the Chinese, and sunk in the same manner from time immemorial.

In answer to a question from the President, Mr. Simpson described the process now so much practised for sinking wells through bad strata by means of cast-iron cylinders; excavating the earth from within the cylinder by an instrument called a "miser," which is a conical iron shell with a valve opening inwards; it is suspended by iron rods 1½ inch square, and worked from the level of the ground without pumping up the water: it is not uncommon to excavate to a depth exceeding 100 feet in that manner. The "miser" can bring up a cubic yard of earth each time it is raised. Cast iron cylinders are

preferable to brick shafts, which frequently hang up, and in that case give much trouble, whereas if the iron cylinders do not descend freely, they will bear the application of considerable force to drive them down. They are frequently forced through the indurated ferruginous gravel. Light planking is also sometimes used, particularly in such cases as in the well he is now sinking at Chelsea, which is 20 feet square, lined throughout with 3-inch planking. It has reached the quick sand at a depth of 32 feet, and will be stopped there.

Mr. Davison had just completed a well at Messrs. Truman and Hanbury's brewery, with cast iron cylinders, 8 feet diameter, and 193 feet deep, an account of which he promised to present to the Institution.

The President was now sinking a set of cast iron cylinders through sand which was liable to be washed away; they were to be filled with concrete and used as the foundation for a lighthouse at the Point of Air. An account of the construction was, he believed, preparing for the Institution.

"A Historical Account of Copper Sheathing for Vessels." By J. J. Wilkinson.

The two former papers by the same author,* treated of Wood and Lead Sheathing for Ships: the present communication gives in the introduction a general account of Copper as a metal; the localities supplying it; the uses to which it has been applied, from the earliest period to the present time; and the relative estimation in which copper of various countries is held on account of its degree of purity, its ductility, or its better preparation, in which latter particular British copper is stated to be pre-eminent.—An epitome is then given of a return to the House of Commons; whence it appears that in 1832, into Swansea alone, there was imported 4350 cwts. of unwrought metal, and 419,604 cwts. of ore, and that there was exported during the same year, of British metal, 153,742 cwts., and foreign metal 112,830 cwts. Copper from Sweden is considered more malleable than that from Hungary; but the former is not so good as British metal, as it contains a portion of iron.

Copious extracts are made from "Knowles's Naval Architecture," whence is quoted the first recorded use of copper sheathing upon the "Alarm" frigate, in 1761; at that period it was believed that sea water had little action upon pure copper, and the rapid decay of the partial sheathing of certain ships was attributed to the impurity of the metal. Experience showed, however, that pure copper, like that employed on the "Tartar," could be destroyed in the short space of four years, while the sheathing of the "Batavia," an old Dutch man-of-war, and of the "Plymouth" yacht, was perfect after 24 and 27 years' service; in both the latter there was an alloy of $\frac{1}{16}$ th part of zinc.

Much information is given on the rolling of copper sheets; the dimensions; the weight per square foot of different gauges, and the uses to which the various kinds are applied: as also on the quantities of metal used for sheathing. The "Neptune," of 120 guns, was cased with 4738 sheets, weighing altogether 17 tons 19 cwts.

The use of copper sheathing is to protect the wood from destruction by the worm, and to prevent the adhesion of weeds, barnacles, &c. which impede the sailing of the vessel. On the first introduction of copper, it was used in conjunction with iron bolts and other fastenings; these soon oxidated, and serious accidents occurred. It was advised in consequence that all the bolts should be of copper or mixed metal. The attention of the Government was directed to the subject, and Sir Humphrey Davy was appointed to experiment upon specimens of metal of different qualities. He soon discovered that when two dissimilar metals are in contact and immersed in sea-water, a voltaic effect is produced which occasions a rapid corrosion of the more oxidable metal, while the other remains uninjured. In 1824 Sir Humphrey Davy communicated to the Government that he had discovered a means of preventing the corrosion of the copper by rendering it electro-negative. This he proposed to effect by protectors of zinc, iron, or any other easily oxidable metal: after a variety of experiments he determined that the protectors should consist of six bars of cast iron, whose united surface should be $\frac{1}{16}$ th part of the area of the copper exposed to the action of the sea water: two of them were placed midships on the keel of the ship, two on the bows, and two on the stern about three feet under water. As far as the philosophical fact was concerned, the result was conclusive, as the copper suffered no waste. Inconveniences, however, arose which had not been foreseen: as the copper did not oxidate, its whole surface was speedily covered with barnacles and sea weeds, which collected in such quantities as to impede the sailing of the vessels, and adhered so fast that in removing them the copper was frequently torn away: the protectors were therefore abandoned, in 1826, for all vessels on service, but were still used for the ships lying up in harbour; the bottoms of these became, however, so foul, that in 1828 the system was entirely abandoned. After the protectors had been for some months on the ships' bottoms, it was found that on the outer surface a red oxide was formed, and beneath it, for some depth, a substance resembling plumbago; this substance, having sulphate of iron for one of its constituents, when laid upon any inflammable body, caused spontaneous combustion: a similar result was obtained by Mr. F. Daniel in 1817, while experimenting upon cast iron, by solution in dilute muriatic acid. Protectors of various kinds have been tried in the French navy, and in the United States; but generally with doubtful success.

A list of all the patents for copper and other sheathing, as well as means of preventing corrosion, &c., is then given at great length: the gradual progress of the application of copper sheathing, first to ships of the Royal Navy, then to Indiamen, to Transports, and finally to Merchant Ships, is then traced. It appears that of the vessels which enter the Thames, one-fifth are sheathed with copper and its alloys; of vessels at Liverpool, eight-tenths are coppered. The precautions for preserving uncoppered vessels from the "Teredo navalis" are then described: and coal-tar pitch is mentioned as the most effective substitute for sheathing.

Copper sheathing appears to be entirely neglected for vessels in the coal trade, although it is singular that the "Teredo" is found in every port to which coals are carried, south of the Tees; in the Thames, as high up as Gravesend, and northward as far as Whitby; traces of the ravages of the "Teredo navalis," and of the "Limnoria terebrans," have at various periods been found, from the north of Scotland and Ireland, on almost every coast to the Cape of Good Hope and Van Diemen's Land, in the Eastern hemisphere: and in the Western hemisphere, from the river St. Lawrence to Staten Island near the Terra del Fuego, almost in the Polar Sea; so that although this maritime scourge is rifest in warm climates, yet cold latitudes are not exempt from it.

Remarks.—Mr. Lowe was pleased to find that the use of coal-tar pitch for shipping was advantageously mentioned: he was convinced that it would be found very superior to vegetable pitch: he had seen comparative experiments tried on board an India ship, and the result was, that the timber which had been coated with the former was preserved both from the worm and from decay, while that which was covered with the latter had suffered from both. He attributed the preservative quality of the coal-tar pitch to the quantity of sulpho-cyanic, or sulpho-prussic acid, which it contained.

Mr. Horne had used coal-tar extensively on wood, but found that it produced decay, which he attributed to the ammonia contained in it.

Lieutenant Oldfield alluded to Renwick's patent, for saturating timber with coal-oil: he had seen specimens of piles at New York, which, when prepared by Renwick's process, perfectly resisted the attacks of the "Teredo navalis," in the same situations where "kyanized piles" had been entirely destroyed.

Mr. Bethell confirmed Lieutenant Oldfield's statement. Coal-oil was a powerful preservative when properly prepared and applied: he objected to the use of ammonia in any shape, as it rotted timber very fast. In experiments he had made, previously to taking out his patent for preparing timber with coal-oil, he observed that wood coated with common coal-tar soon turned brown, and decay ensued: ammonia produced the same appearance and effect. If any vegetable fibrous substance, such as peat, was sprinkled with ammonia, it speedily rotted, and became a rich black earth. In the Mediterranean, the native ship owners used nothing but coal-tar pitch for their vessels; they were cleaned and well tarred twice a year, and the worm seldom made any ravages, although unprepared timber in those latitudes was destroyed in a very short time. The refined coal-tar, as manufactured in London, is purified from ammonia by distillation, and found an excellent coating for wood. The oil of tar, used in Mr. Bethell's process, is likewise purified from ammonia.

Mr. Parkes conceived that diluted ammonia must be meant as recommended for agricultural purposes, and not the ammoniacal liquor as it came from the gas-works; the former, when used with discretion, properly diluted, and to certain soils, was an active stimulant in cultivation, but the latter contained matter which was very prejudicial.

Mr. Bethell observed that ammoniacal liquor, when diluted with three parts of water, had been found to succeed perfectly with peaty soils. Nearly all the sal ammoniac of commerce is now made from the ammoniacal liquor from gas-works.

Mr. Hawkins remarked, that it could be readily understood that the proportion of ammonia used would regulate the effect to be produced; as in the case of gypsum, of which two bushels per acre was a good manure; but in some places fifteen or twenty bushels per acre had been tried, and of course a complete failure had ensued.

Mr. Parkes replied, that gypsum was commonly used in Yorkshire, and habit had dictated the proportions so well that it seemed to be the best manure the farmers possessed there.

Mr. Taylor recalled the conversation to the subject of the Paper on Copper Sheathing; from which many curious facts might be drawn. The ancient specimens of copper sheets had endured longer than the modern: the former contained an alloy of $\frac{1}{16}$ th part of zinc. The "Munts" metal, which is now being extensively used, contains alloy of the same material, but in a larger proportion. The inequality of manufactured copper had perplexed the chemist and the manufacturer for full forty years; and after all their researches and experiments, it would appear that the chemistry of the manufacture of copper and of iron was not understood. Mr. Taylor had been consulted by Sir John Henslowe on the subject, and he had recommended assaying the sheets instead of receiving them by the appearance of their surfaces, as was the usual mode. Dr. Faraday and Mr. Richard Phillips had made an extensive series of experiments for Mr. Vivian, and Mr. Farquhar had carefully analysed various specimens; but all these eminent men failed in discovering any chemical difference between the copper which had endured well and that which had been rapidly destroyed. Sheets of copper rolled the same day, under apparently similar circumstances, differed materially in quality. In the process of "polling," which is carried on by stirring about the copper while in a fluid state with poles of green wood, producing ebullition, whether

* Minutes of Proceedings, vol. 4, for 1841, pp. 318 and 357.

the operation is continued too long or too short a time, the metal becomes brittle, and the quality cannot be recovered. Less copper is now exported from Russia, because the attention of the miners is directed to the gold mines. Mr. Taylor attributed the superiority of the quality of the foreign copper to the ore being smelted with charcoal; whereas English copper is smelted with bituminous coal, frequently containing sulphur.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

April 18.—This meeting was attended by the President, Earl de Grey, who, having left his vice-royalty to attend to his parliamentary labours, took the opportunity of being present. The attendance was most numerous.

A paper was read by Mr. Hosking upon "*The Composition and Construction of Bridges*," the conclusion of which was obliged to be reserved for another meeting, on account of the other business of the evening. After the lecture his Lordship addressed the meeting, alluding to the happy union of the two societies, which had always been an object of his earnest wishes. The articles of union were, he said, satisfactory and advantageous to both societies, and the Institute had received an accession to its collection of a large number of valuable plans, drawings, casts and books. He also adverted to the accession of H. R. H. Prince Albert as Patron of the Institution, and then stated that he had a pleasing duty to perform in presenting the Soanean medal to Mr. J. W. Papworth, Associate, for his design of the restoration of Crosby Hall. It afforded him, he said, additional pleasure to present this medal to that young architect in the presence of his father, who was one of the oldest members of the Institute; and had the good fortune to see his honourable career followed up by his son. In addition to the medal there was a sum of 10 guineas presented by Miss Hackett, the owner of Crosby Hall.

After the conclusion of the business of the meeting there were some beautiful specimens of Keene's cement exhibited, consisting of inlaid paving in various colours, capitals of columns, and other applications of the material for architectural purposes; they were presented by Messrs. White & Son. A specimen of Caen stone was laid on the table; the price stated at which it could be delivered on the Thames was 1s. 10d. per cubic foot.

ACADEMY OF SCIENCES.

Feb. 28.—M. Dufresnoy read a report on some researches by M. Paillette upon the metalliferous districts of Calabria, and the north of Sicily. It appeared that the mines now worked in those districts were not opened previous to 1720, and that before this period the mineral riches of the countries in question had been very imperfectly known to, or at least little used by, the inhabitants, and even the Romans. It was about 1720 that some German miners were employed by Charles VI. to look for metallic veins; their operations assumed a certain degree of importance about 1753; but thirty years later they were almost entirely abandoned. Most of the metalliferous formations of southern Italy consist of small veins, resembling those of Auvergne and the Limousin. Tables of the quantity of metal produced by the various mines now worked accompanied these researches.

A memoir was read by M. Combes, on the sulphureous hot springs of Hamman-Eskouin, near Bona, in Africa. They burst forth on a small plateau, which is covered by a white crust of the mineral matter deposited by their water, and they form round each orifice small cones, from the summits of which the water flows. Their average heat is from 78 to 80 degrees of Reaumur, or from 207½ to 212 Fahrenheit—boiling point. It is only 200 or 300 paces from the spot where the waters of these springs join a mountain stream of cold water, that their heat becomes reduced enough to allow of people bathing in them. They are highly sulphureous, and send up immense clouds of steam. The numbers of people who resort to them for all kinds of complaints are considerable.

March 7.—M. Arago informed the Academy of the result of some observations, lately made with great care, for ascertaining the exact height of the summit of the lantern of the Pantheon above the lowest point, or zero, of the water scale at the Pont de la Tournelle, and also the exact height of the latter point above the level of the sea in the Channel. It appeared that these heights were 117 mètres 60 centimètres, and 25 mètres 76 centimètres (or 385 ft. 10 in. and 84 ft. 6 in.) respectively. M. Arago stated, the object of this was to serve for the settlement of the exact levels of all points of the capital, with a view to a more accurate system of drainage; and further, that the Municipal Council had decided on having the altitude of the soil, above the zero of the scale at the Pont de la Tournelle, marked at a very great number of points in the capital, and engraved on plates, which would be affixed to public buildings or houses of a certain solidity of construction, at the points where the altitudes would be taken.

M. Beaumont-Beaupré laid on the table the 5th part of the great hydrographical survey of the French coast, on which he has been occupied several years. Captain Berard presented the Academy with the general table of observations made on board the *Uranus*, during the late voyage to and from the Island of Bourbon. They related principally to the temperature of the ocean.

M. Chazailon communicated some researches on tides, and the level of the

ocean. He had found that the analytical expression, used by Laplace, for calculating the height of the tide was incomplete.

M. Francoeur read a paper on a new instrument, constructed by himself, for measuring the strength of distilled liquors.

A model was exhibited to the members by M. Sorel, for fixing zinc on iron by a new application of the voltaic pile.

March 21.—A communication was read from M. Amédée-Durand, "*On a New Mode of Constructing Windmills*." The invention of M. Durand consists chiefly in imparting to the sails of the mill their impelling force in a way resembling that which is experienced in the mode of sailing a vessel. The action of the wind striking from behind bears upon a point beyond the centre of the pivot, and tends to keep the shaft in a parallel direction with the current of air, the sails being constantly maintained at a right angle with the wind. By this new system the sails, which are six in number, are not, like those of the common mills in use, supported upon framework, but are attached and spread in the same manner as those of a vessel. They are so disposed that their whole surfaces may be acted upon so long as the wind, augmented in effect by their total surface, is inferior to the weight of a counterpoise, which tends constantly to keep it in its normal position. When the wind exceeds this limit, the counterpoise comes into action, and so changes the quantity of surface exposed, that the machinery may continue to perform its functions without any acceleration of motion beyond what is requisite. M. Durand states that his invention has been submitted to the test of experience, several mills so constructed having for years past been in operation, and effectually resisted the most violent storms.

March 28.—A report, by M. Chevreuil, was read, on a paper, by M. Ebelhelm, respecting the manufacture of iron. M. Ebelhelm's paper was principally on the construction of blast-furnaces, &c. M. Ebelhelm states that he is satisfied, from a series of experiments, that the present mode of constructing furnaces is as near to perfection as possible, but that nearly two-thirds of the combustibles employed pass off in gas, and that there would be great economy and advantage in a contrivance for preserving this gas, and making use of it in the process of smelting. The paper, however, leaves the question of the precise and best mode of obtaining this result still doubtful.

A paper, by M. Gaudin, on photographic drawing, was read. This gentleman announces, that he has succeeded in obtaining perfect impressions, and more rapidly, without the use of the iodine-box, by exposing the plate to the action of a single compound of iodine, of his own preparation, much richer than what is now used in the uncertain photographic apparatus of the iodine-box.

M. Viou communicated to the Academy a new mode of raising vessels sunk in deep water. His apparatus consists of a covered, but light and airtight frame work, which he calls the *hydrostat*. The process is commenced by allowing the water to rush in and fill the *hydrostat*, which of course sinks until it reaches the object it is intended to raise. The valves are now closed, and the apparatus fixed by means of chains or ropes to the vessel. A stop-cock, connected with a pipe, is opened, and this pipe communicates with two recipients on a stage, or platform, erected on a boat, or vessel, near the spot. One of these recipients contains an acid, and the other carbonate of lime, and a communication between them is established, so as to keep up a sufficient supply of carbonic acid gas, which passes through the pipe into the *hydrostat*, and displaces the water. The *hydrostat*, now filled with a light gas, will naturally rise to the surface, if its volume be large enough to drag with it the body to which it is attached.

[The following words were, by accident, omitted at the conclusion of our last month's Report, p. 137:—"be effaced also, and the forgery detected."]

ART-UNION SOCIETY.—The annual meeting for the distribution of prizes was held at Drury Lane Theatre, on Tuesday, 26th ult., when a most interesting report was read, we believe from the pen of Mr. Godwin, and from which we learn that there are 11,119 subscribers and the amount of subscriptions is £12,905. The house was crowded to excess, and many hundreds were forced to go away for want of room. In consequence of the absence of the Duke of Cambridge, the chair was taken by Mr. Benjamin Bond Cabbell. The prizes distributed were 240 in number, varying from 10l. to 400l. We regretted to observe that there seemed a disposition to stifle inquiry, for when one or two members rose to ask some very necessary questions, they were immediately checked; as, however, only one meeting is held in the year, we think that some facility should be given to subscribers to ask for public information; it is the only way to prevent abuse creeping into the proceedings of so useful an association.

The Anti John Scott Russell.—We have witnessed the surprising performance of this small vessel, fitted with Beale's patent rotary engine. The speed of the boat averages upwards of 10 miles per hour, although the engine is little larger than 18 in. diameter, and 12 in. broad. We had intended to have given the drawings of the engine and boiler, together with some particulars of its construction, and the quantity of fuel consumed; but we have deferred doing so until we have had another opportunity of witnessing the performance of the engine. To all who feel an interest in the rotary engine we recommend their attention to that of Mr. Beale: it is extremely simple, and cannot easily get out of order.

REVIEWS.

A Treatise on Fresco, Encaustic, and Tempera Painting. By EUGENIO LATILLA, Mem. Soc. Brit. Art. London: 1842.

In the artistic movement which has been communicated to architecture, the discussion as to the best mode of decorating the New Houses of Parliament has been one of the main features. Here we find two parties formed—the architects having declared themselves for the introduction of mural decoration, and the artists opposing it, or admitting only of oil painting as the proper medium. The architects look upon this subject as not only likely to give a more artistical tendency to their art, but as promising to elevate art itself. To this are opposed the large body of the artists, who, devoted to portrait, landscape, or conversation subjects, having but a limited view of their own art, and being incapable of estimating that of others, and being above all things ignorant of fresco, reject in the strongest terms either the applicability of this medium, or the utility—nay, even possibility—of the existence of high art. They know that the intimate acquaintance with the human form, the breadth and grandeur of outline, and the firmness of touch, required for fresco, are qualifications which their previous studies have denied to them; accustomed also to compose on a small scale, they fear the gigantic efforts of historical art. To such an extent does this ignorance, do these prejudices prevail, that we firmly believe, that did the fate of the decoration of the Houses of Parliament depend on the fiat of the Royal Academy, that by a large majority all idea of it would be rejected. This feeling is to be regretted, as it will tend but too strongly to fortify the inclination for German artists, already manifested by some members of the Royal Commission; for if English artists declare that they cannot execute fresco, the Commissioners will naturally turn to the Bavarians, who are but too ready to assert their proficiency. Under such circumstances it is to be expected that the most exaggerated and unfounded statements with regard to fresco have been given out, which are so ably met by Mr. Severn in another part of the Journal, that we do not think it necessary ourselves to refute them. If they think that with so many examples before their eyes in the public buildings of London, that the Commissioners will ever trust to oil as the vehicle for decoration, the artists are most grievously mistaken. Its blackness its varnished surface, its partial effect, and its perishability, would alone suffice to ensure its rejection, and throw us upon the mercy of the whitewasher, or of the carver and gilder. Fortunately, however, the question does not depend for determination upon the artist: the architect has his vote. The artist on this occasion is only the subordinate; and mural decoration is a question which has come within the attributions of the architect from the earliest period. The architect will, upon turning to Vitruvius, find the instructions and mechanical details which, the same in principle and practice, prevailed in the classic period and in modern days; he will find that until the artist commences his work on the wet plaster, the whole matter is exclusively in his hands; and that even then it is his duty to direct and supervise, to see that the harmony of the design is maintained, and that the several parts are correspondent to the whole. Fortunately also, the architect is well qualified to judge between the respective media. He will look to their general effect, to their durability, to their capability of harmonizing with his own labours; and it becomes no question as to preference between the marmoratum with which fresco is incorporated, or a scaly covering of decomposing oil. If the Houses of Parliament are to be decorated at all, it is evident it must be by fresco or encaustic, or not at all; and we beg our readers not to be diverted from the right course by any clamour or misrepresentations of the artists, but to judge for themselves.

When this question was first agitated, it was the general impression that we must either fall back on the Germans, or commence from the rudiments a new school of our own. The result, however, has been to show that we have many artists already practically versed in fresco; and many others have since made themselves acquainted with it. Among those who have practised this art, two are to be distinguished. The first is Mr. Parris, who has long devoted himself to it, and whose views on the subject have been communicated to the Institute, and published in our Journal; and the second is Mr. Latilla, late President of the Society of British Artists, also an old practitioner in this country, and student in Italy, and author of the work before us. Among other artists who have publicly given their countenance to fresco, are Mr. Haydon, who has availed himself of the instruction of Mr. Latilla; Mr. Severn of Rome, the friend of Keats the poet, and author of the valuable discourse on mural decoration which we insert in our present

number; Mr. Baker, of Bath; Mr. Bell, of Manchester; and Mr. Lane; the latter of whom are all practically acquainted with it. We learn also on Mr. Haydon's authority, that the late Sir David Wilkie was an advocate for fresco, having twenty years ago recommended the former artist to apply himself to it. Those who wish to see some account of the labours of these artists, will, in some of our recent volumes, find descriptions of works both by Mr. Latilla and Mr. Parris.

The work to which we now wish to direct the attention of our readers, we must warn them beforehand is to be studied Hebrewwise—from the end—for Mr. Latilla has unfortunately tacked to it some preliminary chapters, which, not being copious enough to enter into the whole history of the art, come on the ear with all the weariness of common-places. The reader must therefore plunge *in mediu*, and he will there find a good description of the practical part of mural decoration, which, although meagre, is sound in its teachings. Mural decoration is of four kinds—fresco, encaustic, tempera, and kalsamine; to the last of which, although certainly of little importance, we see no allusion in Mr. Latilla's work. The first consideration in all cases is to be directed to the stuccos, of which there are three layers requisite for fresco. The first process Vitruvius calls *Trullisatio*, or rough plaster, and was performed by the Romans with a plaster of 1 part lime, 2 parts rough river sand, and 1 part pounded brick and tile. The second process is named *Arenatum*, or sand mortar, the Roman composition of which was 1 part lime and 2 parts river sand, of which they used three successive coats, each laid on while the preceding one was damp. Much depends on the *Arenatum* being well prepared: if only one layer be used, the plaster will be liable to crack and decay. For the *Arenatum*, the Italian fresco workers of the fifteenth century sometimes used *pozzolano* mixed with *Treverthe* lime, in the proportion of 2 of lime to 1 of *pozzolano*; and Mr. Latilla says that he has used with great success good Roman cement and stone lime, which he has found to give a firm basis to work upon, and greater brilliancy to the colours. The third process was called *Marmoratum*, or marble mortar, being composed of 1 part lime and 2 parts marble dust, of which three thin coats are laid on in different degrees of fineness, the coarsest first. It must be so tempered as in working not to adhere to the trowel, but to leave it clean and free from mortar. There is a difference between this and the *Arenatum*, for each layer of the *Marmoratum* should be allowed to dry before the succeeding one is applied. If the layer of *Marmoratum* should be single only, the plaster will be apt to crack and scale off, and the design will be deficient in brilliancy. The thickness of the several layers of plaster in the Baths of Titus is about an inch and a quarter, but the Italians diminished this thickness in their works, to the serious prejudice of their durability; neither did they pay such attention as the Greeks and Romans to the proper working of the mortars.

Having for the present dismissed the architect, we have to consider the duties of the artist, to whom Mr. Latilla, as it seems, paradoxically recommends to paint in all the ornament first; but he appears, on reflection, to be in the right, assigning as his reason for this recommendation, that it is easier to harmonize subject to ornament than ornament to subject, the subjects also being intrusted sometimes to different artists, so that the arabesques form an excellent key for the tone and colour of the historical painter. For every part cartoons must be prepared of one or two layers of thick paper, on which the design is sketched with charcoal, and then painted in tempera with colours. This outline is transferred on the walls, usually by tracing the cartoon with an etching point; but this always leaves furrows on the stucco, and Mr. Latilla recommends in preference pricking out the outline with an etching needle, and then pouncing it with charcoal powder on the fresco. A portion of the outline being traced or pounced on the wet stucco, the painting begins, which must be executed in sections, as a head or a limb at a time, and each part rapidly, so that the colours may incorporate with the lime: no retouching can be allowed, with due regard to effect. The arabesques having been painted in, Mr. Latilla prescribes that the blank cartoons should be fixed in their respective situations, and then the general design to be sketched in, as a better judgment can be formed of it when up. Again, when all the cartoons have been drawn, he recommends that they should be affixed in their positions, so that the full effect of the whole may be seen; a measure which is necessary when several artists are employed, and which shows what alterations and improvements are required to harmonize the whole. The whole work, we say, and the general superintendence of it, should be committed to the architect, who is the party responsible for the entire effect, and who is best aware of what agrees with his design.

Encaustic, one of the most ancient methods practised by the Greeks, is a particular favourite with Mr. Latilla. Of the ancient practice but little is known, and, we are sorry to say, that of its modern applicability as little.

Mr. Latilla, with much apparent reason, seems to think that it was executed with a mixture of wax and oil; and he has applied this mixture with success in the banquetting-room of the Duke of Beaufort's mansion, in which he has happily united the freshness, brilliancy, and freedom from glare of fresco, with the richness and facility of oil. Mr. Latilla's process is a good one, and one deserving of greater extension; but we do not think that it is the ancient encaustic, if, indeed, the discovery of the true encaustic be not a chimera which, if found, would not be worth the finding. From all we have seen, we fear it would be so.

Tempera was practised by the Egyptians and the Greeks, and also in the English cathedrals; and, according to Vasari, was executed with yolk of egg mixed up with the milky juice of the fig-tree, and then used with colours ground up in water. Mr. Latilla says that the fig-tree juice is not essential, but that we have a substitute for it in the spurge or wartwort, which yields a milky juice applicable for the purpose. Kalsamine is tempera with a conservative surface; but neither of them are so durable under the operation of the atmosphere as fresco and encaustic.

Mr. Latilla mentions a curious circumstance with regard to fresco, that in the course of drying it frequently exhibits an alarming appearance, the colour looking patchy and faint, and a white mould rising to the surface. In the course of two or three months, various changes succeed each other till the picture almost entirely disappears; but as the plaster dries, it shows itself with more than pristine beauty. Michael Angelo was so troubled with this phenomenon while painting the Sistine Chapel, that he was about in disgust to throw up the work, until he was assured by Julian da San Gallo of the temporary nature of this operation, and the causes of it.

A great many experiments are now being made as to the best materials for cement; and we understand that Mr. Alfred Francis, in the course of a long investigation on this subject, has even succeeded in getting mural painting to withstand the operation of the atmosphere. The subject is important, and we hope the results of these experiments will be communicated to the public.

A Manual of the Steam Engine. By RICHARD D. HOBLYN, A.M., Oxon. London: Webster and Geary, 1842.

We should be glad to know for what class of readers Mr. Hoblyn's book is designed. The professional engineer can hardly be supposed to be edified by an *omnium gatherum* of the most trite and superficial remarks on steam of the last half century, and the general reader has nothing further to desire after the admirable popular treatise on the steam engine by Dr. Lardner. There is no redeeming quality about Mr. Hoblyn's book. He does not treat of any new branch of inquiry connected with the steam engine, nor of any new application of steam power. He has adduced no new facts, supplied no new investigations; he has neither shortened nor simplified any pre-existing analysis, nor stated more felicitously the nature of any particular movement, agency, or combination. The only thing he has succeeded in showing is, that a man may set up for an instructor without any tolerable acquaintance with the subject he professes to teach. A popular treatise upon the steam engine is a complete superfluity, unless its merits be transcendent. Mediocrity is unpardonable where great excellence has already been attained; and Dr. Lardner's treatise is a standard which it is fatal to come short of, and hardly possible to surpass.

An Account of Patent and other Methods of Preventing or Consuming Smoke, &c. By WILLIAM WEST, Professional Chemist, Leeds.

THIS pamphlet is a collection of various schemes for consuming or preventing smoke, as promulgated by the several projectors at a public meeting held at Leeds in January last. It is difficult from such a heterogeneous mass of materials to analyse them without entering into the merits or demerits of each, which would occupy the whole of our Journal for the next three months, we therefore refer our readers to Mr. West's pamphlet, and let them judge for themselves; however, we cannot allow this notice to pass without observing that too much praise cannot be awarded to Mr. Eddison, the spirited individual who called the meeting together, and who has devoted so much of his valuable time and labour to an investigation of the subject. It does not appear that the committee who met to consider of the several plans submitted, or Mr. West, the compiler of the pamphlet before us, have come to any determination as to which of the various plans is the best, and have, like ourselves left it to the public to form their own opinion.

Height of Paris above the Level of the Ocean.—It appears, from geodetical operations and direct levelling, that the zero of the hydrometric scale at the Pont de Tournelle is 26.25 metres above the mean level of the ocean.

THE ATMOSPHERIC RAILWAY.

SIR—I am of opinion that the annexed passages, taken from the report to the Committee of Privy Council on Atmospheric Railways, by Col. Sir Frederick Smith, R.E., and Professor Barlow ought to be placed together to enable the public to appreciate the value of one of the conclusions given at page 6 line 1 of their report.

"Secondly, the expence of the formation of the line in cuttings, embankments, bridges, tunnels and rails, will be very little less than for equal lengths of railway to be worked by locomotive engines; but the total cost of the works will be much greater, owing to the expence of providing and laying the atmospheric tube and erecting stationary engines."

The latter part of the conclusion refers to Samuda's estimate of £4000 for single and £7000 for a double line for the atmospheric apparatus for impelling the trains; but the question whether a less expensive line might not be formed by means of steeper gradients, worked by a proportional vacuum, appears to be dependent on the working force of different vacuums, and it ought to be decided by the ratio of the increased cost of higher vacuums in comparison with the increased resistance of higher gradients, and this subject is adverted to at page 4 line 11 of the report.

"In the pamphlets circulated by the patentees," credit is taken "for two important items, which we cannot altogether admit.———" Another questionable item is the reduced expence of cuttings and embankments, it being assumed by the patentees that not having to take the locomotive up a plane, much steeper gradients may be introduced than in present lines; that a great part of the power of a heavy locomotive is expended in overcoming its own gravity and resistance in ascending steep planes is certainly true; and it is equally true that on the atmospheric principle the whole additional force is exerted on the load itself. This is unquestionably an advantage, but still we think its importance has been greatly overrated."

At the bottom of page 5 the commissioners remark, "Having stated our own views, and having given in the appendix the experimental results and investigations on which they are founded." On referring to the appendix I find they state at page 11, line 1, "We were desirous, if possible, to ascertain the working force which different vacuums possessed of urging a train forward, but we failed of obtaining on this part of our inquiry any useful results, the engine not having sufficient power to preserve the vacuum constant."

The details of four experiments are then inserted, and it is added, "No conclusions can be drawn from these four experiments except that by the falling of the mercury, it is clear that with all the force thrown upon the engine, it was inadequate to the duty it had to perform."

I apprehend the case made out by the Report respecting a reduction of expence in the formation of the line itself, for an atmospheric railway, stands thus:—1st, the commissioners *think* the patentees have overrated the advantage that may be derived from the introduction of steeper gradients or portions of the line to be worked by a higher than average vacuum otherwise employed, and in the consequent reduction of the cost of the line. 2nd, that they admit the additional force of such increased vacuum is expended on the load itself. 3rd, that in consequence of the inability of the engine to preserve a constant vacuum, they were unable to obtain data for the determination of the limits within which the steeper gradients suggested by the patentees could be rendered available with the higher vacuums, or under what conditions the larger tube also suggested by the patentees for a low vacuum would be required on steeper gradients. 4th, that their conclusion, that a very small reduction of the expence of the formation of the line itself can be effected, is not founded on any evidence as yet submitted to the public, but rests on their own opinions. Time and trial must decide on the respective values of the assertions of the patentees and the thoughts of the commissioners. A jury, by the usage of this country, is directed to give the prisoner the benefit of a doubt. Commissioners, acting on different principles, report against an inventor.

Y

REGULATION OF CHIMNEYS.

SIR—On reading over the Act for the future regulation of Chimnies, with a view clearly to understand its intention, but which is not very easy, my attention was arrested by the observation "*or of greater length than four feet out of the wall;*" and I have in vain tried to decide in my own mind what our legislators mean by it, as the flue must of necessity (as far as I can understand) be in the wall; and why a less length than four feet should be exempt from the rule as to the size of the flue. Perhaps you, Sir, or some of your readers, will be good enough to remark on this in your next.

I have not heard whether the Architect's Institute have yet acted on your suggestion of September last.

I am, Sir,
Your obedient servant,
A SUBSCRIBER.

March 24.

[It appears to us that why the length of 4 ft. out of the wall is exempted, is to give an opportunity of introducing chimney shafts and pots with a contracted opening.—EDITOR.]

THE NEW TARIFF ON TIMBER, DEALS, &c.

THE important change that is likely to be effected in the duties on the above articles has induced us to give the following information relative to the present and the proposed new duties; likewise a table which shows more immediately the differences between the old and new duties on foreign deals. We did not consider that it was necessary to extend the table to deals from British possessions, as the proposed new duties are so very trifling, and can be easily calculated from the cubical contents we have given of the various lengths of planks, deals, and battens in the table.

PRESENT DUTIES ON TIMBER AND DEALS IMPORTED INTO GREAT BRITAIN FROM FOREIGN COUNTRIES AND BRITISH POSSESSIONS.

	Foreign.	British.
BATTENS, not exceeding 7 inches wide and 2½ in. in thickness		
per 120	£ s. d.	£ s. d.
“ Ends, under 6 feet long	3 0 0	0 7 6
“ 6 ft. in length and not exceeding 16 ft.	10 0 0	1 0 0
“ exceeding 16 ft. and not exceeding 21 ft.	11 10 0	1 3 0
“ 21 ft. “ 45 ft.	20 0 0	2 0 0
DEALS, above 7 inches wide and not exceeding 3½ in. in thickness

EXPLOSIONS OF STEAM BOILERS.

THE calamitous accident which occurred lately in the Clyde has recalled public attention to this subject, and there can hardly be a doubt that unless means can be devised of rendering explosions less frequent, there will be some legislative enactment upon the subject. We should desire much to see the causes of explosions investigated at the instance and under the direction of the Steam Association, with the view of inducing the voluntary adoption of measures calculated to avert such disasters. The influence of example and the force of opinion would be productive of far greater amelioration than any legislative interference without giving rise to any of the confusion, irritation, and injury which such an interference would create. From a variety of circumstances which have come to our knowledge, we are thoroughly persuaded that the most prolific source of explosions is a deficiency of water in the boiler. There can hardly be a doubt that this was the cause of the late explosion of the Telegraph, in the Clyde, as well as of the Victoria in the Thames, and the Union in the Humber. Explosions generally take place just after the engines have been set to work after having been stopped for some time. In consequence of the inaction of the feed-pump whilst the engine is at rest, no water enters the boiler, and the quantity of water left in the boiler is rapidly diminished by evaporation until the water level falls below the top of the flues. The upper part of the flues consequently becomes red hot, and the rapid generation of steam or the decomposition of the water, immediately that the renewed action of the feed-pump sends a quantity of water upon the red hot plates, induces so great and so sudden a pressure, that explosion immediately ensues. The obvious remedy for this state of things is to furnish every boiler with a contrivance to maintain the level of the water by self-acting means, so that whether the engines are at work or whether they are stationary, the surface of the water in the boiler is preserved at a uniform height without the necessity of any alteration on the part of the engineer. It is perfectly possible to accomplish this by a suitable mechanism, and no vessel ought, we conceive, to be without some species of apparatus to attain this end. We have seen one contrivance which is not merely perfectly efficacious, but extremely simple, and which we would recommend to the notice of those interested in steam navigation. This contrivance is, we understand, the work of Mr. Robert Sinclair, of Gould Square. There may be other mechanisms that we know not of, equally efficacious, and the merits of all should be investigated and the best chosen. But whether viewed as a measure of safety in preventing explosions or fire from an overheating of the flues, or as a measure of economy in obviating the fearful expense so often arising from boilers being burnt, as is the technical phrase; we are strongly of opinion that some automatic feeding contrivance ought to be resorted to, and we can speak with much confidence of the merits of that particular contrivance we have alluded to.

PATENT VALVE CLOSETS.

SIR—I beg to solicit your attention to an improvement in the Valve (or Bramah's) Water Closet, patented by W. Beetsom. Its decided advantage will be clearly seen from the following engravings.

A

The Valve Closet is allowed by all scientific men to be the best in use: but from the fact of the valve of the common (or Bramah's) closet lying horizontally, unless the handle is pulled up all the distance, it only opens PARTLY; and when opened the whole distance, the valve and axle are exposed to the paper, &c. catching upon it. By this invention the faults of the present closet are quite counteracted.

The principal improvement consists in the valve at the bottom of the basin being placed in a sloping position, which position allows the valve to open quite out of the way, and prevents paper, &c. catching upon it.

B

C

A Shows Beetsom's Closet in section, with the valve closed.

B Shows how far the improved valve opens when the handle is raised.

C Shows the common (or Bramah's) valve open.

The improved valve.

Bramah's valve.

The dotted line shows the valve partly open, which is its position when the handle is raised quite up.

The valve of the improved closet cannot be opened, as shown by the dotted line of figure C, as the slightest movement of the handle opens it perpendicular, or as far as the common closet, when its handle is pulled quite up.

Another improvement consists of a valve being placed in the waste arm, (or overflow pipe); the use of this valve is to prevent smell from arising, should the part trapped be dried up, which is often the case.

I am,
Yours obediently,
F. ROE.

70, Strand.

MR. S. SEAWARD'S MEMOIR ON AUXILIARY STEAM POWER.

SIR—In your review of Mr. Seaward's memoir on Auxiliary Steam Power, you quote as from the 5th Part of Vol. III. of the Transactions of the Institution of Civil Engineers, the following passage, "the employment of a quadruple amount of steam power would not double the speed, although in theory this is assumed to be the fact." I have read the article over very carefully, and cannot find such a passage; the only one resembling it is at page 386. "The immediate consequence of this disproportionate increase of weight is a greater immersed section of the vessel, and a necessary increase of resistance offered to her motion, so that the force required to propel her through the water must always increase with the power employed, and not even cubing the steam power would produce double the velocity." It would be only just to make this correction in your next number.

M. INST. C. E.

[The only answer we have to give to the above communication is to request any of our readers who may be desirous to examine for themselves, to call at our office and inspect the copy of the Transactions in our possession, and there they will find the passage as quoted by us, word for word; at the same time we are bound to say that we have seen another copy of the Society's Transactions, since the appearance of our review, and in that copy the paragraph is transmogrified into the one last quoted by our correspondent above.—EDITOR.]

ON ARCHITECTURAL CRITICISM.

ADDRESSED TO J. L.

AN apology is certainly due from me to J. L., inasmuch as I addressed J. L. when Ditto, it seems, was the mystical person to whom, a reply being necessary, I should have replied. My hope of pardon from J. L. rests upon that gentleman's perceiving that the word Ditto, coming immediately after his initials, was the cause of my being led into the mistake alluded to. Upon the general manner of my writing, which J. L. condemns for want of simplicity, I feel compelled to be silent—readers being generally better able than writers are to determine such a question—though of course it cannot be supposed that I could, in reason, by bowing to the opinion of J. L., a nameless writer, confess to a fault by no means small. For although I would allow it to be very possible, that the revelation of my ideas upon criticism, may not have been sufficiently clear to every reader, yet I would submit to the intellectual critic, whether the necessity of fitting thoughts, often requiring a wide field for their display, into the columns of a periodical, would not account for occasional obscurity. It would be unreasonable for a person like myself, freely animadverting on others, to hope to escape animadversion himself, but if there are, amongst the intelligent correspondents of this Journal, any who have tried their skill on similar themes in a periodical, I feel certain of their indulgence. Leaving this matter to the discernment of just people, it only becomes me to notice the paragraph complained of, with the view of proving that the paragraph is not obscure and unmeaning, although J. L. may not perceive its force. I would remark that, unconcerned as J. L. was in the remark which led to that paragraph, and innocent as he was necessarily of the feeling, or affectation of the feeling, of contempt for me, which feeling, or its affectation, Ditto displayed in his remark, I was provoked to notice, he could not feel the edge of a reply which cut only as it insinuated what it was I despised. This manner of answering, if obscure, has been a favourite method of reply amongst orators and poets of every age, and for this simple reason, that it allows a speaker or writer to represent his own feelings, at the same time as he ridicules or expresses contempt for those of others.

April, 1842.

FREDERICK EAST.

ON THE MEASUREMENT OF STONE BRIDGES.

SIR—In your last number a correspondent asks the best way of finding the contents of a stone bridge. No general formula can be found, but the following remarks—equally applicable to brick—will, I think, be found pretty general.

Begin by the piers, abutments, &c. It is best to keep the footings separate. The following formulæ are useful for the contents of the arch:—

For a semicircle, W. D. (R. π .)

For a segment, W. D. (R. π .) $\frac{180}{\omega}$

where W=width of arch; D=the thickness (measured, of course, on a radius); R=internal radius + half the thickness: $\pi=3.1415$; ω =No. of degrees in arc. The backing and walls resting on arch have a curved outline. For this a straight line may be substituted, taking care to equalize the portions left out with those added; or they may be supposed to be carried down to the springing line, and from the contents thus found, the arch and archway (calculated as above) must be deducted. Many, and particularly railway bridges, are symmetrical about 2 axes; it is in this case the easiest way to take out the cubic contents in one quarter, and multiply by 4 for the total contents. Almost all bridges are symmetrical about 1 axis; in this case, of course the multiplier is 2. All the different parts should be kept separate, and their title put on the side, as it facilitates revision; and besides, many parts being repeated, saves the trouble of repeating the calculations.

I am, Sir,
Yours, &c.
A. H. P.

April 11, 1842.

STEAM NAVIGATION.

THE WEST INDIA MAIL STEAM PACKET COMPANY.

It pains us much to be unable to say anything calculated to repress the growing conviction that this is a most perilous enterprise—not that there is anything inherent in the nature of the scheme to render it necessarily disastrous, but that the management is so supremely injudicious as would be fatal to any project, even the most promising. It is true, that this evil admits of a simple and obvious remedy, but the constitution of the human mind is such, that men prefer to attribute calamities to any cause except their own ignorance or indiscretion; and a fault once committed, is oftener defended than acknowledged. On this account, although the means of amelioration are attainable, our hopes of spontaneous amendment are but feeble; and certain it is, that the accomplishment of such a thorough reformation as the

exigency of the case demands, requires much fortitude upon the part of the directors, as it involves the admission of past errors and the dismissal of every cherished prejudice and prepossession. It is right, however, that the opportunity of reformation should be afforded, and we are willing to render our best advice and assistance towards so happy a consummation. It would grieve us much, that any calamity should fall upon this most spirited and arduous enterprise. Such an event would operate most perniciously upon the whole interest embarked in steam navigation, and paralyze the spirit of commercial adventure in the same channel. Should no improvement have been carried into effect before next month, it is our intention to enter into a thorough analysis of the character and management of this enterprise; and we are only prevented from doing so at once by the apprehension that our exposures might occasion such inconveniences as the obduracy of wrong-headedness alone deserves.

We entreat the respectable directors of this undertaking to give their immediate attention to this subject. Let them look to the dangers of their present position—dangers from which neither magisterial pomp nor inexperienced precipitancy can possibly save them. Was it ever before heard of, that the utmost skill and experience should be deemed unessential to the success of an enterprise of extraordinary magnitude and difficulty, though found indispensable to the prosperity of more limited and less adventurous schemes? and can the directors confidently say, that in the whole compass of their immense establishment, there is a single man to be found experienced in the conduct of commercial steam navigation upon the large scale? Is such an enterprise as this to be expected to succeed in the hands of inexperienced persons, even although those persons may unite much general ability with much plausible pretension? What are the fruits of such administration? There is scarcely a newspaper which does not teem with accounts of mails late—vessels wrecked, or missing—quarrels abroad—passengers almost starved—and vessels following one another by mistake—and at an interval of a few hours across the Atlantic? whilst, at other times, the greatest inconvenience and distress are occasioned by merchants being left without their remittances for months together, and correspondents without their letters. Do the directors imagine that such things will be long endured, or is it to their interest or credit that such things should exist? But all this is as nothing when compared with the loss which must arise from the working of the vessels under existing conditions. One vessel comes in with twelve or fourteen passengers—another, with five or six, bringing an income of a few hundred pounds, perhaps, when the expense of a voyage must be several thousands. There is the mail money, 'tis true; but how far will the mail money go towards paying for coal, insurance, and wear and tear? But we are departing from our intimated intention. We think the enterprise beneficially accomplishable, but not under existing circumstances; and unless those circumstances are so changed as to give the undertaking a fair chance of success, we shall, in our next number, draw the attention of the proprietary and the public to the subject.

"THE PRECURSOR."

This is really an extraordinary steam vessel. We were prepared to expect a handsome and an efficient vessel, from Mr. Robert Napier, but we could hardly have anticipated that a vessel built for the ordinary purposes of commercial transport, should have been capable of making her way from the Clyde to the Thames in so short a time as 70 hours. A rate of progress, by the unaided agency of steam, such as the performance of this voyage involves, is in the case of large sea-going vessels, not only unprecedented, but almost incredible, and demands the most unequivocal testimony for its authentication. Under the influence of this sentiment, we have examined the "Precursor's" log: we have also derived collateral information from unbiased and authentic sources; and we have much confidence in the exactitude of the information we now purpose to lay before our readers.

The "Precursor" started from Roseneath, a place on the Clyde, immediately opposite to Greenock, on the 8th of April, at 35 minutes after 1, and arrived at Blackwall at 5 minutes after 1, on the 11th. The total time occupied between the clock light, a little below Greenock, and Blackwall, was including stoppages, &c. 71 hours; and if we make a deduction of one hour for the several stoppages, inclusive of 50 minutes, during which the vessel was going quite slow, waiting for the pilot, the actual time occupied between the clock and Blackwall will be only 70 hours. The distance between those two points we have heard severally estimated at 775 and 800 geographical miles. Our own measurements, upon a good chart, induce us to believe the latter estimate the more correct, and 800 divided by 70 is equal to 11½ geographical miles per hour nearly. This is an extremely high average, particularly as the voyage was accomplished without any aid from sails, and the progress of the vessel, during a considerable part of it, was retarded by a head-wind of such intensity as to have reduced the speed of the engines from 15 to 13 revolutions per minute. We are informed, that her speed, when unimpeded by an adverse wind, was 15 geographical miles per hour.

The "Precursor" is the first of a line of large steam vessels about to be established between Calcutta and Suez, in continuation of the Peninsular and Oriental Company's line of steam communication between Southampton and Alexandria. The engines are of the common side-lever construction, by Mr.

Robert Napier, of Glasgow, who, we understand, contracted for the entire vessel. They are of the collective power of 500 horses: the burthen of the vessel is equal to 1751 tons, N. M.

We shall, next month, more fully describe the dimensions and construction of the engines and vessel.

Il Peloro.—This is a compact steam vessel, built by Mr. Pitcher for the Neapolitan Government, for conveying the mails. Her dimensions are 130 ft. in length between perpendiculars, 19 ft. 6½ in. moulded breadth, and 20 ft. 2½ in. extreme breadth; depth in engine room 11 ft. 2½ in.; burden 252 tons, B.M. She is fitted with a pair of 50 horse engines, by Messrs. Boulton, Watt, and Co.; cylinders 3 ft. 3½ in. diameter, and stroke 3½ ft.; paddle-wheels 15 ft. 6 in. diameter; length of boards 8 ft., and 16 in. wide. She performed, at an experimental trip on the Thames, on Thursday, 21st. ult., an average velocity of 10½ miles, consuming a very small proportion of fuel. The indicator figures showed a vacuum of 12 to 13 lb., with a pressure of 3½ lb. of steam.

NEW CHURCHES, &c.

Stockport.—The opening of the New Unitarian Church, a unique and very elegant edifice, took place on 23rd. March last. The site is in St. Peter's Square. The body of the chapel is a parallelogram, externally 63 by 44 ft. with a projection at the south end about 30 ft. wide by 14 ft., in which is placed the principal entrance, and the staircases to the boys' and girls' schools, and to the organ gallery. At the northerly end there is also a projection about 24 ft. wide, by 6 ft., in which is placed the pulpit and the communion. The interior of the chapel will accommodate 400 persons: there are no galleries except for the organ and choir, in the recess at the south end. The exterior projection at the south end is flanked by double bold buttresses, having circular shafts at their external angles, with bases and capitals to the same, the whole being surmounted with triangular headed canopies, out of which proceed octagonal turrets, surmounted by pinnacles, ending in carved finials, about 50 feet above the level of the street, and having an enriched corbel table round the foot of each pinnacle. Betwixt the buttresses to the south front there is a splayed recess, surmounted with a pointed arched head, with hood mould thereto, terminating upon carved heads. In the lower part of this recess is placed the principal entrance to the chapel; it has splayed jambs, and a pointed arched head, surmounted by a moulded triangular headed canopy, terminating with a carved finial. Over the door are three lancet windows, united together by their hood moulds, which terminate upon foliated bosses, the centre window being higher than the side ones, and the upper end of the canopy of the door stands out quite clear of the lower part of the centre window. The gable in the south front has a moulded canopy terminating with a carved finial on the apex. The ends of the chapel, extending beyond the projections to the same, are finished with a moulded coping, terminating in moulded canopies at their lower ends. The sides of the chapel are divided into six compartments, by broad flat buttresses, with one set off, and terminating at the upper ends with the overhanging parapet, which is supported by moulded stone corbels betwixt them, with cast iron moulded gutters thereon, and in each compartment is placed a lancet window. The upper base moulding is carried along the sides of the building, and in the space under it, betwixt the buttresses, are placed the windows to give light to the schools. The whole of the exterior of the building is faced with stone, hammer-dressed, except the ashlar dressings and moulded work, which is tooled; the stone for the former is from the Kerridge delphs; and for the latter, from the Yorkshire delphs; and it is worth while noticing the greatly improved effect which the narrow courses from the Kerridge delphs give to the building from the usually wider courses which are obtained from other delphs. The entire cost of the building, including the additional expense incurred by the peculiar nature of the foundations, will not exceed £3000. The chapel has been designed by, and built under the superintendence of Mr. Richard Tattersall, Architect, of Manchester.

Ireland.—A Roman Catholic Chapel at Dundalk was opened on the anniversary of the Apostle of Ireland. It is constructed of hewn granite stone, from the neighbouring quarries, and is of the pointed style, which prevailed during the latter part of the thirteenth century. It consists of a nave and side aisles, divided by two rows of clustered pillars, having moulded capitals: from which spring lofty pointed arches, supporting a clerestory pierced with windows, which give light to the body of the church. The nave, or centre division, projects both in the front and rear several feet beyond the ends of the side aisles, having two lofty bell-towers, octagonal in form, composed of five stages, or compartments, with enriched cornices, panels, and mouldings. The upper divisions of these towers are extremely light and ornamental, having panels of pierced tracery, and slender, graduated, angular buttresses, which rise very boldly above the perforated parapet of the roof, and are crowned with embraured parapet, pinnacles, and finials. The principal entrance to the church is in the north front, having three spacious doorways of great beauty. The grand entrance is between the octagon turrets, and is deeply recessed; the imposts are ornamented by well relieved mouldings and small pillars; from the capitals rise rich mouldings and tracery, which surrounds and intersects the pointed arch with a very pleasing effect. On either side of this entrance are placed ornamental niches, having angular buttresses and canopies, intended for the reception of full length statues. Immediately above the great doorway rises a magnificent window, 17 ft. wide by 30 ft. in height, having moulded imposts boldly recessed. The arch is surmounted by a hood-moulding, sustained at the springing by sculptured heads. The open part has six divisions, subdivided by an ornamental tran-

som, which separates the window into twelve lights. The head is filled with delicate and varied tracery of very beautiful design. In the centre of the pointed gable is an ornamental opening, moulded and surrounded by a drip-stone, which is filled with louvres, for the purpose of admitting air to the roof. Above is a large enriched raking-cornice, supporting a parapet of open panelled work, from whose acutely-pointed apex rises an ornamental cross. The lateral doorways are recessed with drip-stones resting on corbels. The spandrels are filled with carved shields and cinquefoil tracery. The flanks of the building are sustained by an equal number of graduated buttresses of three stages, which rise above the embrasured parapet, and terminate in pinnacles and finials. Between the several divisions of these buttresses the wall is pierced with large openings, having pointed arches and hood-mouldings; each opening is divided by moulded stone mullions and a transom into six lights, and the heads filled with tracery work. The south end of the church is in a plainer style than the principal, or north front. The body projects here very boldly, and is to be the Sacristy: it is flanked by octagonal towers. The great window which lights the Sanctuary is 36 ft. high, by 15 wide, divided and subdivided into fifteen openings or lights: the head is filled with very rich ornamental ramifying tracery. The clerestory which rises above the roof of the side aisles, is equally divided in the sides by buttresses and lofty pinnacles: between each buttress is a pointed window, filled in with mullions and tracery of cut stone. The dimensions of the building taken over the walls are 178 ft. from north to south, by 78 ft. in breadth; the height to the upper pinnacles of the nave 75 ft.; the elevation of the front towers is upwards of 86 ft. The rear towers are not yet finished; but the finish is intended to correspond, in every respect, with that of the front. When the edifice is completed, it will, without doubt, rank among the best of our modern ecclesiastical structures, both for magnitude and beauty of design. We have often greatly admired buildings planned and superintended by our distinguished and excellent townsman. But regard to truth, as well as justice to professional merit, requires us to state that, for so far, Dundalk chapel is decidedly the *chef-d'œuvre* of Thomas J. Duff, Esq.—*Newry Paper*.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 31ST MARCH TO 28TH APRIL, 1842.

Six Months allowed for Enrolment.

JOSEPH CLIBILD DANIELL, of Tiverton Mills, near Bath, for "improvements in making and preparing food for cattle."—Sealed March 31.

JULIUS SEYBEL, of Golden-square, Middlesex, chemist, for "improvements in the manufacture of sulphate of soda and chlorine."—March 31.

WILLIAM LIVERSIDGE TRIPPETT, of Charlton-upon-Medlock, Lancaster, agent, for "improvements in looms for weaving by hand or by power."—March 31.

JOHN BEVAN, of Whitehead's-grove, Chelsea, gent., for "an improved mode of expelling the air from certain cases or vessels used for the preservation of various articles of food."—April 6.

JAMES SMITH, of Deanstone Works, Kilmadock, Perth, cotton spinner, and JAMES BUCHANAN, of the city of Glasgow, merchant, for "improvements applicable to the preparing and spinning of cotton, wool, flax, hemp, and other fibrous substances."—April 6.

JOHN READ, of Regent's Circus, mechanist, HENRY PUTLAND, of Hurst Green, Sussex, farmer, and CHARLES WOODS, of Fore-street, Cripplegate, commercial traveller, for "improvements in the construction and make of driving reins, harness, bridles, and reins, and in bridles and reins for riding."—April 6.

JEAN GEORGE SIRE CLARKE, of Euston-grove, engineer, for "improvements in supplying and regulating air to the furnaces of locomotive engines." A communication.—April 6.

THOMAS CLIVE, of Birmingham, iron-founder, for "certain improvements in the construction of candlesticks."—April 7.

JOHN ANTHONY TIELENS, of Fenchurch-street, merchant, for "improvements in machinery or apparatus for knitting." A communication.—April 7.

MARC CARLOTTI, of Little Argyle-street, Regent-street, Gent., for "certain improvements in the construction and manufacture of boots, half-boots, shoes, clogs, and galoshes." A communication.—May 8.

WILLIAM FALCONER, of Clapham Common, Gent., for "improvements in apparatus for attaching buttons and fasteners to gloves and parts of garments."—April 13.

JOHN BYRON DAWES, of Trafalgar-square, Charing-cross, Middlesex, Gent., for "a certain improved chemical composition or compositions, to be employed in the preparation of glass or other media of light."—April 15.

JOHN LAMB, of Kidderminster, machinist, for "improvements in engines to be worked by steam, air, gas, or vapours, which improvements are also applicable to pumps for raising or forcing water, air, or other fluids."—April 15.

THOMAS RICHARDS, of Liverpool, bookbinder, for "certain improvements in the art of bookbinding, and also in machinery or apparatus to be employed therein."—April 15.

ALFRED JEFFERY, of Lloyd's-street, Pentonville, Gent., for "a new method of preparing masts, spars, and other wood, for ship-building and other purposes."—April 15.

CHARLES FARINA, of Leicester-square, chemist, for "a new method of manufacturing soap, candles, and sealing-wax."—April 15.

KENT KINGDON, of Exeter, cabinet-maker, for "certain improvements in impressing and embossing patterns on silk, cotton, and other wools or felled fabrics."—April 21.

WILLIAM NOEL, of Jermyn-street, St. James', boot and shoe-maker, for "certain improvements in the manufacture of boots and shoes."—April 21.

ALPHONSE DE TROISBRIEUX, of Great Russell-street, Bloomsbury, Gent., for "improvements in lithographic and other printing-presses." A communication.—April 21.

OTTO ROTTON, of Gracechurch-street, Doctor of Medicine, for "certain improvements in machinery or apparatus for spinning cotton, wool, silk, and other fibrous substances." A communication.—April 26.

WILLIAM WOOD, of Wilton, manufacturer, for "a new mode of weaving carpeting and other figured fabrics."—April 26.

SZYMUS COCKING, of Birmingham, draftsman, for "certain improvements in the production of light, by the burning of oil, tallow, and wax, and in the apparatus for regulating and extinguishing the same." Partly a communication.—April 26.

RAOUL ARMAND JOSEPH JEAN COMTE DE LA CHATRE, of Leicester-square, RICHARD TAPPIN CLARIDGE, of Weymouth-street, Gent., and RICHARD HODGSON, of Salisbury-street, Strand, Gent., for "improvements in preparing surfaces of fabrics, to be used in covering roofs, floors, and other surfaces." A communication.—April 26.

HENRY ROBINSON PALMER, of Great George-street, Westminster, civil engineer, for "an improvement or improvements in the construction of roofs, and other parts of buildings; and also for the application of corrugated plates or sheets of metal to certain purposes, for which such sheets or plates have not heretofore been used."—April 26.

JOSEPH MEGE, of Keppel-street, Russell-square, merchant, for "improvements in the making or constructing of trousers." A communication.—April 26.

JOHN HENRY PAPE, of Grosvenor-street, Bond-street, piano-forte-maker, for "improvements in carriages, and in the construction of wheels."—April 28.

JOHN VARLEY, of Colne, Lancashire, and EDMONSON VARLEY, of the same place, cotton manufacturer, for "certain improvements in steam engines."—April 28.

WILLIAM LOSH, of Newcastle-on-Tyne, Esq., for "improvements in the construction of wheels for carriages and locomotive engines intended to be employed on railways."—April 28.

The following Patents were accidentally omitted in the list of last month.

JOHN GREEN, Jun., of Newtown, Worcester, farmer, for "improvements in machinery or apparatus for cutting or reducing turnips, mangel wurzel, carrots, and other roots, for food for horned cattle, horses, and other animals."—March 7.

JOHN GEORGE BODMER, of Manchester, engineer, for "improvements in machinery or apparatus for cleaning, carding, roving, and spinning cotton and other fibrous substances."—March 7.

JAMES READMAN, of Islington, gent., for "an improvement or improvements in the barometer."—March 7.

JOHN DUNCAN, of Great George-street, Westminster, gent., for "improvements in machinery for excavating soil." A communication.—March 7.

JOHN WARRICK, of Lawrence Pountney Lane, Cannon-street, merchant, for "an apparatus called a gasoscope, and intended to show the presence of bi-carburetted hydrogen gas (the gas used for lighting) in mines, wells, houses, buildings, rooms, and vaults; and consequently to prevent the explosions and accidents liable to be produced by the said gas."—March 7.

FRANCIS KANE, of Cumberland-street, Middlesex Hospital, mechanic, for "improvements in the construction of fastenings for the parts of bedsteads and other frames."—March 7.

SIR FRANCIS DESANGES, of Upper Seymour-street, Portman-square, Knight, and ANGUISH HONOUR AUGUSTUS DURANT, of Long Castle, Shropshire, Esq., for improvements in apparatus for sweeping and cleansing chimneys or flues, and extinguishing fires therein, which they intend to call 'remoneur.'—March 7.

ROBERT FRAMPTON, of Cleveland-street, Fitzroy-square, coach maker, for "improvements in the construction of hinges."—March 7.

TO CORRESPONDENTS.

O. T. Both his communications have been received; one, or both, if possible, will appear next month. We hope that, notwithstanding our delay in inserting his papers, he will continue to forward us the result of his labours.

Mr. Moxham's experiments on the strength and deflexion of wood and iron will appear next month.

There are several papers which we have been obliged to postpone; likewise our remarks upon Mr. Williams' boiler projects, and other subjects. We will endeavor to clear off all arrears in the next Journal.

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, III, and IV, may be had, bound in cloth, price £1 each Volume.

The best test of excellence which all can
that machinery must be admitted to be the best which continues to
do the greatest quantity of work at the least expense. But the ad-
judication of this high authority is only to be obtained in the lapse of
years—it is with difficulty to be obtained at all—and even then it is
likely to be the resultant of a variety of circumstances of which the
quality of the machinery is only one. Nevertheless, any information

MARINE ENGINES BY MESSRS. MILLER, RAVENHILL & Co.

PATENTED BY JOSEPH MILLER.

(With an Engraving, Plate VI.)

The object of this arrangement of machinery is to economise room, and this object is certainly very completely attained; a power of upwards of 300 horses occupying only 8 feet in the length of the vessel and 18 feet in the breadth. There are, it is true, certain counter-weighing disadvantages—for example, the connecting rods, as well as the eccentric rods, are short, occasioning not merely an increased friction in the working of those parts, but disturbing the movement proper to the slide valves, and there is the want of that equilibrium of weight so nicely preserved by the side lever principle. These defects attach either wholly or partially to all engines of the direct action description; so that the gain in space and lightness is not a gain without any deduction. In these engines they are mitigated as much as possible by placing the cranks at such an angle as to preserve the balance as nearly as may be, and by such a configuration of the upper and under slide-valve faces as will neutralize the effect of the distorted movement, consequent upon the shortness of the connecting and eccentric rods.

The nature of Messrs. Miller & Co.'s arrangement is rendered so obvious by the accompanying drawing, that any detailed explanation of it would be a mere waste of words. The connecting rods are attached to the tops of the piston rods, the latter being maintained in the perpendicular position by means of guides G G, Fig. 3, in which cross heads work, one of which is shown at H, Fig. 1. There are two air-pumps, and the vessel in which condensation is accomplished, and which fills the whole space between the cylinders, is divided by a diaphragm so as to make it, in fact, two condensers, each with its own air-pump immersed in it, so that no sole plate is requisite; great strength is attained with a moderate weight of material, and a large power is compressible (so to speak) into a very narrow compass. The air-pumps are of brass, and the buckets are wrought by the cranks C C on the intermediate shaft, and the tops of the air-pump rods are kept in the upright position by the guides g g. M M are the man-hole doors of the condensers; B B are strong flanges or brackets, through which the bolts pass for securing the engines to the vessel's bottom.

We understand Messrs. Miller and Ravenhill are now constructing a pair of these engines for the British government, the cylinders of which are 65 inches in diameter, and the length of the stroke 5 feet = 308 H.P.; also a pair for the French government, the cylinders of which are 68 inches in diameter, and the length of the stroke 5 ft. 6 in. = 340 H.P. One pair of these engines is nearly completed.

The general character of Messrs. Miller & Co.'s machinery may, we conceive, be summed up in a few words. With a destitution of embellishment which, in some cases, we are disposed to regard as the result of too severe a philosophy, there is an excellence of materials and workmanship, and a superiority of proportion and arrangement, united with an efficiency and an economy of performance which we do not believe have ever been surpassed. In the minutest details of the work, as well as in its leading features, there are evidences of a profound acquaintance with the subject, both in its practical and philosophical relations. Where such anxiety exists to render the quality of work unexceptionable, and is united with so much ability and so much experience, it is impossible that its quality should be any other than of the very first description; and it is therefore far from surprising that Messrs. Miller's machinery should be esteemed so highly. The best test of excellence which all can understand is Time; for that machinery must be admitted to be the best which continues to do the greatest quantity of work at the least expense. But the adjudication of this high authority is only to be obtained in the lapse of years—it is with difficulty to be obtained at all—and even then it is likely to be the resultant of a variety of circumstances of which the quality of the machinery is only one. Nevertheless, any information

we may be able to gather respecting the actual performance of the machinery of any maker must, with all its liabilities to error, be admitted to be a valuable aid towards enabling us to arrive at a right conclusion respecting the probable qualities of any machinery of a similar kind he may propose to furnish.

EXPERIMENTS ON THE STRENGTH OF TIMBER AND IRON.

We have been favoured with the following interesting experiments on the strength of wood and iron, by Mr. Moxham, of Neath; they were made in the presence of a party of gentlemen for the purpose of illustrating the laws of increased strength, &c., in relation to increased dimensions; they are important for the purpose of testing the formulæ of Tredgold, and likewise the Tables given in the fourth volume of the *Journal*, pages 79 to 82.

AMERICAN YELLOW PINE TIMBER.

Experiments on bars of American yellow pine, straight-grained, dry, and free from knots.

	Suspended weight.	Deflection.
Experiment 1.—Bar $\frac{3}{4}$ in. square, and 5 ft. between bearings, on which it rested loosely, the weight being suspended from the middle.	16 lb.	1.5 in.
	24	2.25
	32	3.00
	34	3.31
	36	3.81
	38	4.44
	40	4.75

In about 5 minutes this increased to 6.25 in., after which the piece broke with the same weight: the first symptoms of fracture were shown by cracks indicating a compression, from the top edge down to about the middle.

	32 lb.	3.75 in.
	48	3.3
	64	3.75
	96	1.12
	128	1.5
	136	1.69
	144 [increased to 2'	
	152 ditto	2.25
	160	2.62
	[and incr. to	2.87
	166	3.75

3 $\frac{3}{4}$ in. was the greatest measured deflection, and with this weight the bar broke, the first signs of giving way being near the top. When broken, the fracture was comparatively smooth at the top and about $\frac{3}{4}$ of the way down, from compression; while about $\frac{1}{4}$ at the bottom was ragged from the fibres being violently torn apart.

Exp. 3.—Yellow pine, as before, 5 ft. long, 2 $\frac{1}{2}$ in. deep, and $\frac{3}{4}$ wide.	128 lb.	0.5 in.
	256	1.06
	320	broke it.

The depth which appeared to have been compressed and that which was extended were nearly the same as in the last experiment.

Exp. 4.—Yellow pine, 5 ft. long, triangular bar, the edge or vertex being down, 1 $\frac{1}{2}$ in. wide on the base of the angle, and 1 $\frac{1}{4}$ in. deep in the centre.	16 lb.	0.19 in.
	32	0.43
	64	1.03
	96	1.75
	104	2.
	112	broke it.

Exp. 5.—Yellow pine, 5 ft. long, same section as last experiment, the edge or vertex of the angle placed upwards.	16 lb.	0.31 in.
	32	0.57
	64	1.10
	96	2.37
	[increased to	2.62
	100 & broke it	3.

	16 lb.	0.75 in.
	32	1.5
	64	3.0
	72	3.94
	80	5.31
	[and incr. to	6.0
	82	7.25
	[incr. to 7.81, & broke.	

CAST IRON.

The iron in this and the four following experiments was the same, being the best Welsh cold-blast iron, melted in an air furnace. Half the weight of the bar to be added to the weight suspended from the middle.

Exp. 7.—Cast iron bar, 5 ft. long between bearings, weight suspended from the middle, and ends loose as before; bar $\frac{3}{4}$ in. and $\frac{1}{4}$ square, or .78 in.; weight of bar between bearings 9 lb.	112 lb.	1.375 in.
	168	1.81
	224	2.69
	252	[3.22, & broke it.

	112 lb.	0.125 in.
	224	0.31
	336	0.64
	448	0.94
	504	1.125
	532	1.19
	560	Broke it in

half a minute. This was probably strengthened by the fastening from which

the weight was suspended being screwed tight, instead of left loose: it broke 2 in. from the middle.

Exp. 9.—5 ft. between bearings of this section, cast as it was placed in the experiment; weight 10 lb.	112 lb.	0.16 in.
	224	.37
	336	.69
	448	.94
	504	1.12
	560	1.82
	616	1.5
	636	broke it.

Exp. 10.—Bar cast from same pattern as above, but cast, and placed in the experiment with the thin part down, the reverse of experiment 9. This bar weighed $\frac{1}{4}$ lb. lighter than the above, though there was no perceptible difference in the section, and it was equally sound.

	112 lb.	0.42 in.
	224	0.67
	336	1.00
	392	The bar bore this for a few seconds only.

Exp. 11.—Bar 5 ft. between bearings, $\frac{7}{8}$ (.875) in. thick, 2 $\frac{1}{4}$ (2.03) in. deep in the middle, and .91 at the bearings, the under side having the same curvature as a parabola, which makes the average depth 1.66 in.; weight of bar between bearings 11 lb.	112 lb.	0.16 in.
	224	0.31
	336	0.43
	448	0.60
	560	0.75
	672	0.92
	728	1.00
	784	1.07
	840	1.19
	868	broke it.

* 3 in. from the middle on one side, and 16 in. from the middle on the opposite side; showing that there was more than a proportionate strength at the ends of the bar.

In Exp. 13 the bar was straight at top and hollowed out on the under side, having a section at the middle of 1 $\frac{1}{4}$ in. deep, and $\frac{1}{4}$ in. thick, and at the ends of 2 $\frac{1}{4}$ in. and the same thickness. It was placed with the straight edge on the top, the ends being loose; and with a weight of 224 lb. + 5 $\frac{1}{4}$ (half weight of bar,) the deflection was 0.9 in. It was then taken up, and replaced with the curved edge up, the ends still loose; and with 224 lb. + 5 $\frac{1}{4}$ (half weight of bar,) the deflection was 0.94 in. It broke with less than 252 lb., but the quality of iron in this was not quite equal to that in the preceding experiments: making allowance for this, we should find its strength not greater, if so great, as that of a bar the same length and thickness, and of a uniform depth of 1 $\frac{1}{4}$ in. The weight between bearings was 10 $\frac{1}{2}$ lb.

Exp. 14.—Cast iron bar, a part of the one broken in experiment 7th, placed 2 ft. 6 in. between bearings; ends loose, &c., as before; weight of bar 4 lb. between bearings.	224 lb.	0.31 in.
	336	0.47
	448	0.62
	504	0.72
	560	0.86
	588	0.98

Broke in putting on an additional 14 lb.

MISTAKES AND MISREPRESENTATIONS.

IN speaking of our number for April, 1841, the *Bauzeitung* has fallen into a conglomeration of blunders, jumbling different articles and subjects together in the oddest manner possible. "Episodes of Plan on Roman Architecture," it says, "must be passed over by us on account of its length, and because it does not admit of compression; and for the same reason so must also Candidus *Notizen Buch!* Fascic. XXV, which paper consists of fragmentary criticisms, and chiefly upon Professor Hosking's lectures." This is a tolerably pretty specimen of the art of blundering by wholesale! "The Episodes of Plan" and "Roman Architecture" (the latter from the Penny Cyclopaedia,) are two distinct articles, several pages apart from each other. As to the "Note-book," again, that Fasciculus is so very far from being chiefly upon Professor Hosking's lectures, that it only incidentally mentions his name in one of the shortest paragraphs, without saying anything of his lectures at all. But there does happen to be in the same number an article signed S. L., and headed "Candidus' remarks on the lectures of the Professor of Architecture," meaning not remarks by C. himself, but counter-remarks in reply to others he had previously made; nor were those remarks upon the lectures of Professor Hosking, but on the lectures of the Professor of Architecture at the Royal Academy. It will be a mercy if the *Bauzeitung* should not now go and mistake Professor Brown for Professor Cockerell, or jumble all the three Professors together, and compound them into one individual!

VELOCITY OF WATER THROUGH PIPES.

(From Report of Lecture by Dr. Melson in the Midland Counties Herald.)

THE calculations for the head of water necessary to keep up a given velocity for every 100 ft. run of pipe, have been so ably deduced, from experiment, by Mr. Rofe, of the Birmingham Waterworks, that the lecturer could not forego the pleasure of pointing them out a little more in detail, and of giving the tables by which the necessary calculations were effected. The tables were two, and were both deduced from absolute experiment—not from experiments conducted by means of tin tubes of small diameter, fit only for laboratory uses, as there was too much reason to fear many of the tables previously published had been constructed, but from the absolute cast iron tubings themselves, as laid down in Birmingham and its vicinity. The tables were two: in the first, V represents the table of velocities in feet per minute, and T the constant numbers for those velocities:—

V	T
60	8.62
70	11.40
80	14.58
90	17.95
100	21.56
110	25.35
120	29.70
130	34.
140	38.90
150	44.
160	49.50
170	55.66
180	62.13

In the latter D represents the diameter of the pipes in inches, and t the constant numbers for those diameters:—

D	t
3	.028
4	.053
5	.078
6	.104
7	.134

As an application of these tables, the following problem was proposed; it having been premised that the formula for their use was

$$\frac{T}{D \times t} = H$$

where H represents the height, or head of water. It is required, then, to determine what head of water will be necessary to send water by an engine through 1,500 ft. of six-inch pipes to an elevation of 80 ft. at a velocity of 180 ft. per minute. Now, by the table we see that the constant number for 180 ft. velocity is 62.13, and the constant number to be added to 6 inches is .078,

$$\text{and } \frac{62.13}{6.078} = 10.22 \text{ inches.}$$

which is the head of water required to keep up the velocity of 180 ft. per minute for every 100 ft. run; which being multiplied by 15 (the number of hundred yards through which it has to pass), gives 153 in., or 12 ft. 9 in. This, added to 80 ft., will give 92 ft. 9 in. as the column of water which the pump must lift.

MEASUREMENT OF BRIDGES.

THE formula given last month for the contents of a segmental arch was misprinted: it should have been

$$WDR \pi \frac{\omega}{180}$$

where W=width; D=thickness of arch; R=internal radius+ $\frac{1}{2}$ D; $\pi=3.14159$; ω =number of degrees in arc. The following table will facilitate computation.

Table for Segmental Arches and Semi-ellipses.

c	R	ω	$\pi \frac{180}{\omega}$	$\frac{\pi}{2} \cdot \sqrt{\frac{a^2+b^2}{2}}$
2	1	180 0	3.14159	3.14
3	1.62	134 46	2.344	3.99
4	2.50	106 14	1.848	4.98
5	3.62	87 10	1.516	5.96
6	5.00	73 44	1.282	7.01
7	6.62	63 46	1.139	7.80
8	8.50	56 8	.976	8.87
9	10.62	50 8	.883	10.46
10	13.00	45 14	.787	11.09
11	15.62	41 14	.717	12.19
12	18.50	37 50	.658	13.31

The column headed c contains the ratios of the span of the arch to the rise, taken as unity; the corresponding numbers in R are the respective radii. In column ω are the degrees and minutes in the arc.

The column $\pi \frac{180}{\omega}$ multiplied by W D R will give the cubic contents

of the arch. The last column shows the length of semi-ellipses, of which the half-minor axes are unity, and the major axes the figures in column c. This multiplied by the width into the thickness, into the rise, will give the cubic contents of the arch in question.

The best formula for the cubic contents of a tube or cylindrical ring is $L \pi (R^2 - r^2)$ where L=length; R=external radius; r=internal ditto; $\pi=3.14159$. Since the external radius=the internal+the thickness of tube, we have $L \pi (R^2 - r^2) = L \pi (r+d)^2 - r^2 = L (2dr + d^2)$ where d=the thickness. Now, supposing that in an iron pipe d should=half an inch, d² will= $\frac{1}{4}$ of a foot. Neglecting this, as may be safely done for short lengths, the formula becomes

$$L \pi (2dr)$$

ANOTHER COMPETITION AFFAIR.

SIR—I am requested by Mr. East to lay before you the following statement of the disgraceful manner in which he, as a competitor in designs for the new church at Kidderminster, has been treated by the Committee, and their actuary Mr. Boycot. On the 10th of December last an advertisement, of which the following is a copy, appeared in the "Times" Newspaper:—

It is proposed to build a church in the parish of Kidderminster to contain 1250 sittings, of which 850 are to be free. Architects wishing to furnish plans for the same are requested to apply for farther particulars to William Boycot, jun. Esq., solicitor, honorary secretary; and all plans are required to be sent to him on or before Wednesday, the 22nd day of December next.

Kidderminster, Nov. 26, 1841.

You will observe it was published for the first time 14 days after date, thereby affording 12 days for the preparation of designs. As it happened we had at that time more leisure than usual, and made application to the said Mr. Boycot (who, by the way, loses no opportunity of advertising his calling,) for particulars of the advertisement, whereupon we received the following reply:—

SIR—The undermentioned are the particulars relating to the new church to be erected at Kidderminster.

I am, Sir, your obedient servant,

Kidderminster, Dec. 13, 1841.

W. BOYCOT, jun., Sol., Hon. Sec.

1. That the church will be built, subject to the rules and conditions of the incorporated society.
2. That the expense must not exceed £3000.
3. That it be built of stone.
4. That there be a tower.
5. That the architecture be Gothic.
6. That there be a commodious vestry.
7. That there be no chancel.
8. That the pews be deal painted and grained oak colour.
9. That the whole of the galleries be free, and such other portions of the church as may be required to make up the number to 850 free sittings.

P.S. The above are the conditions the Committee resolved upon, but since then they have determined to receive plans of churches including a chance.

Accordingly we set about making the drawings, but it subsequently occurred to us that something ought to be specified as to the terms of competition; whether or not the successful competitor was to superintend the work, or if any premium was to be received for the best design, and we immediately applied for information, in answer to which application the following letter was forwarded us:—

SIR—In answer to yours of yesterday's date, I beg to state that no premium will be given for designs; and whether the successful competitor will be allowed to superintend or not I cannot say, but most likely he will.

I am, Sir, (for Mr. Boycot)

Your obedient servant, GEO. BODDINGTON.

Now, had we not proceeded so far with the drawings as to render them useless for anything else, we should, of course, have declined having anything to do in a matter so strangely conducted; but we hoped they would improve upon acquaintance, and attributed this behaviour to want of good breeding as well as experience. Our designs were accordingly forwarded on the 21st of December, and not having received any communication, we wrote on the 1st of April to inquire whether the Committee had made selection of a design. Two days after this we received the drawings, unaccompanied by any note or acknowledgment, in a most shamefully mutilated state, and bearing evident marks of having been used on the ground. Three days afterwards the following letter came to hand:—

SIR—Your plans were forwarded by coach on Saturday, the Committee having only decided on the 1st instant, and they desire me to thank you for having sent in designs.

I am, Sir, your obedient servant,

Kidderminster, April 5, 1842.

W. BOYCOT, Jun.

As the description of our designs was not returned with the drawings, and not having then received the above letter, I wrote to Mr. Boycot as follows:

SIR—I beg to acknowledge the receipt of our designs for the proposed church at Kidderminster, but the description thereof is not returned, and I shall feel obliged by your forwarding it at your earliest convenience. We feel somewhat surprised at the uncourteous treatment received at the hands of the Committee, no note having accompanied the drawings, stating whether they were approved of or not, and I think that after having detained them for nearly fifteen weeks, a letter of thanks is at the least due to the architect. I should feel obliged by your informing me who is the successful competitor.

I am, Sir, your obedient servant,

WIL. W. WARDELL.

To this letter we received one in reply from Mr. Boycot, expressing surprise at the contents of the above, but not mentioning one word about the successful candidate. The matter then remained silent until Monday, the 11th of April, when, to our great astonishment, we perceived the following advertisement in the "Times":—

To Builders.—Builders desirous of contracting for the erection of the new church at Kidderminster may inspect the plans and specifications, by application to William Boycot, Esq., Solicitor, Kidderminster; and sealed tenders must, with the names of the sureties, be left at his office, addressed to the Committee for building the new church, on or before the 18th of April instant.

In the letter above quoted you will observe that the Committee only decided on the 1st of April. Now is it likely that in nine days an architect could prepare contract drawings, specifications, &c. ready for advertising for tenders? and not only so, but there was no architect's name mentioned in the advertisement. These circumstances aroused our suspicion that the whole affair was one of those disgraceful pieces of chicanery so frequently exposed in your valuable Journal, and determined us to pursue the inquiry of who was the successful competitor; and we accordingly wrote to inquire on the 14th of April, and on the 20th received the following reply:—

Re Kidderminster New Church.

SIR—I duly received your letter, but could not answer it till this day, the Committee having only decided yesterday. The successful architect is Mr. G. Alexander, of London.

I remain Sir, your obedient servant,

Kidderminster, April 20, 1842.

W. BOYCOT, Jun.

Now what are we to understand? for this letter completely contradicts that received on the 6th of April. It was therein stated that the Committee decided on the 1st, and in the last letter he informs us it was on the 19th. Mr. Boycot will surely see the truth of the old adage, " * * * " Probably when Mr. Boycot wrote to us on the 20th he had forgotten the contents of his letter of the 5th. We can hardly imagine that so respectable a member of the profession as Mr. Alexander could have lent himself to anything so unjust and contemptible, but it does appear to us that the advertisement for designs was a mere matter of conformity to the regulations of the Church Commissioners, and that it never was intended to be an open competition or an impartial selection.

I shall leave the matter in your hands, yet I trust, Sir, for the benefit of that profession whose cause you so ably advocate, you will not fail to expose this instance of the manner in which these robberies of professional time are carried on. We do not wish it to be understood that we consider our design had the least claim to preference, or possessed the slightest degree of merit, yet I must confess these extraordinary circumstances, together with the contradictory statements of Mr. Boycot, confirm the opinion that his conduct is the first instance suggested.

I am, Sir,

Your very obedient servant,

WIL. W. WARDELL.

REGULATIONS ON RAILWAYS IN FRANCE.

THE Minister of Public Works, in conformity with the opinion of the committee on steam-engines, has provisionally issued the following orders:—

1. The employment of locomotives on four wheels is forbidden with passengers' trains.

2. Neither tender nor any other carriage on four wheels to be placed at the head of the trains before the locomotives.

3. The locomotives to be placed at the head of the train, and never behind.

This regulation never to be violated, except in case of changing the direction of the trains at the stations, or in case of a train being stopped by accident, and that it should be necessary to send assistance from behind the train; but in such case the speed of the train not to exceed 22 kilometres the hour (13.7 miles).

It is moreover absolutely forbidden to enclose a train between two locomotives, one before and the other behind.

4. Until a better mode shall have been discovered to diminish the effect of shocks and collisions, there shall be placed one wagon without passengers at the head of each train composed of five carriages at most, and of two wagons, when the number of carriages in the train shall exceed five.

5. The passengers' carriages never to be locked.

6. Every railroad company to keep books, in which shall be entered the state and length of service of every axle-tree, whether straight or curved.

7. The Prefect will publish an ordinance, stating the interval at which two trains are to succeed each other.

8. The speed of the trains in their descent from Versailles to Paris on either line not to exceed 39 kilometres per hour. (24 miles.)

Independently of the above measures, the Minister of Public Works has requested the committee on steam engines to examine—

1. Whether in the descent from Versailles to Paris, and in fact in all rapid descents, it would be advisable to prohibit the use of more than one locomotive, and, if not, under what regulations they should be tolerated.

2. To discover the best mode of preventing inflammable matter from being communicated by the locomotives.

The Minister is moreover about to appoint a special commission to make experiments—

1. Upon the degree of perfection to which the axletrees of locomotives may be brought, and the length of time they ought to remain in use.

2. Upon the different means to be employed in order to diminish the effects and danger of collisions on railroads.

STRAWBERRY HILL.

BEALE'S PATENT, 1842.

BEALE'S PATENT.

GROUND PLAN OF HOUSE.

SCALE

THE "ANTI JOHN SCOTT RUSSELL" STEAM BOAT.

(With an Engraving, Plate VII.)

In our last number we slightly alluded to the performance of this vessel, and then stated that we deferred giving the drawings of the engine and the boiler patented by Mr. Beale until we had an opportunity of making a second trial. Since then we have had another trial, when her performance was equally as good as in the first trip. The boat is a small iron vessel, 53 ft. long by 6 ft. beam, and 3 ft. 3 in. deep, and draws 17 in. at stern, and 13 in. fore, or 15 in. mean. The paddle-wheels are 6 ft. 5 in. diameter, out and out, with 10 float boards on each wheel, 2 ft. 9 in. by 7½ in. She is propelled by one rotary steam engine patented by Mr. Beale, and which is delineated in the annexed engraving Plate VII, Fig. 1, drawn to a scale of 1½ in. to a foot. The cylinder is 14 in. diameter, and 9½ in. long (measured transversely) in the clear of the casing. The drum is 12 in. diameter, having 3 indents for the reception of 3 rollers 4½ in. diameter, and 9½ in. long: these perform the office of the piston. At the top is the steam pipe: when the aperture is opened, as shown in the figure, the steam passes down the pipe, and acts against the back of the roller, and presses it forward until it reaches the aperture on the opposite side, where the steam is allowed to escape into the eduction pipe, and thence into the condenser, as indicated by the arrows. It will be observed that the apertures are always open, one for the reception of the steam, and the other for its exhaustion. The admission is regulated by a throttle valve in the steam pipe, before it enters the casing of the engine. The reversing of the engine is extremely simple: it is done by turning the screw, or by a lever which pushes forward the Dalide valve, when it reverses the flow of the steam, which passes through the cylinder in the contrary direction of the arrows. The engine generally makes from 250 to 300 revolutions per minute, and by this rapid motion the centrifugal force causes the rollers to press against the outer casing, and allows the steam to act upon the back of them, as before explained. To the engine of the above boat there are 2 air pumps 8 in. diameter, and 11 in. stroke. The condenser forms a pedestal in the bottom of the boat, upon which the engine and pumps are placed.

The boiler, it will be perceived, is as compact as the engine. The drawing, Fig. 2 in the Plate, is drawn to a scale of ¾ of an inch to the foot. It is cylindrical, 2 ft. 6 in. diameter, and 7 ft. high over all, and contains numerous small tubes about one inch diameter, and an inch apart, through which the heat and smoke pass from the furnace to the chimney immediately over. The area of the grate is about 4 square feet, or half a foot per horse; the water occupies only a very small height of the boiler, the other portion forms a receptacle for the steam. We should think it would be better if the water was kept up to the second cock, otherwise great heating surface is lost. The steam is generally generated to a pressure of 40 to 50 lb. in the boiler. The consumption of coke is stated to be about 60 lb. per hour, depending upon the speed. The air for the supply of the furnace is driven in by the aid of a fan.

For communicating motion to the paddle-wheel there is a pinion wheel on the outside of the shaft or axis of the engine, which drives a larger wheel upon the shaft of the paddle-wheels, in the proportion of 1 to 4½, so that when the engine makes 270 revolutions per minute, the paddle-wheels make 60 revolutions. The total weight of the engine, condenser, air pumps, paddle-wheels, boiler, and water, is 2½ tons.

Having thus described the engine, we shall next proceed to give the particulars of her performance. The first trip we made was from Westminster Bridge to the Old Swan at Chelsea, when she performed the distance (2½ miles) in 20 minutes, against the tide when slack, and back again in 18 minutes, the tide being both ways just upon the turn at low-water. We then went down the river *with the tide*, and performed the distance from Westminster Bridge to London Bridge (2 miles) in 19 minutes; from London Bridge through the Pool to Greenwich Hospital (5 miles) in 39½ minutes. We then tried a measured mile (where the river was clear, from the 4½ to 5½ miles mark), which was done in 6 minutes with the tide.

At the second trial, she performed the distance from Westminster Bridge to Greenwich Hospital (7 miles) in 37 minutes, with the tide.

During the above trips the paddle-wheels varied from 45 to 58 revolutions per minute.

We will now analyse the power of the engine.

The radius of centre of pressure is apparently about 6.75 in., say diameter 13.5 in., and circumference = 42.39 in. by 225 turns per minute = $\frac{9537.75}{12} = 794.8$ feet, say 795 feet per minute.

Area of piston! or exposed part of roller appears to be 2 in. × 9½ = 19 in. area, although it is doubtful if the steam does not enter the space *behind* the roller, and exert its force on that part of the machine. Suppose we take it at 19 in. area, we have for power, at 7 lb. per inch nominal,

$$\frac{19 \times 795 \times 7}{33,000} = 3.2 \text{ horses power.}$$

But this rule is not applicable, as the steam used is as high as 50 lb. or 40 lb., say mean 45 lb. in boiler, perhaps 40 lb. in cylinder or drum. With this pressure the vacuum is probably not more than 20 inches, if so much, but that is matter of experiment only, as it depends on circumstances not before us; suppose it be 20 inches, it will then be equal to 10 lb. We have, Steam pressure = 40 lb. } = 50 lb. effective
Vacuum „ = 10 lb. }

and $\frac{19 \times 795 \times 50}{33,000} = 23$ horses, which may be considered as ACTUAL power, and if this engine is expected to exert *double* its nominal power, as the common reciprocating marine engine does, we have $\frac{23}{2} = 11½$ horses power. Mr. Beale, however, calls it only 8 horse

power; but this difference doubtless arises from our not having hit upon the proper pressure and vacuum, and which experiment only can determine, that is by a steam and vacuum gauge, for we apprehend the common indicator is inapplicable to this engine. The consumption of coke is stated to be about 60 lb. per hour, this for *nominal* power is equal to 5.2 lb. per horse per hour, and for actual power = 2.6 lb. per horse per hour, which is a very small consumption.

The paddle-wheel is 6 ft. 5 in. diameter, boards 7½ inches deep, inner diameter of wheel = 5.2 feet; taking the mean diameter at 50 turns per minute, the velocity will be 10½ miles per hour.

The amount of tear and wear is a question of practice, but the good workmanship which is now common, would obviate many difficulties formerly experienced. The engine is certainly very simple compared with previous patents of the same kind, and is also very powerful in working, and must be very economic in its construction, particularly when used as a non-condensing engine.

Besides the engine on board the "Anti John Scott Russell," Mr. Beale has one of a similar size and description at his manufactory at East Greenwich, worked at the low pressure of 4 to 6 lb.; it stands on the ground, and is hardly perceivable among the numerous machinery in the shop, although it drives the blast fan of a foundry, and sets in motion numerous lathes, planing machinery, drills, &c.

STRAWBERRY HILL.

(With an Engraving, Plate VII.)

AFTER being forgotten, except as recalled to recollection by the reproachfully proverbial term of "Strawberry Hill Gothic," the residence of Horace Walpole has been the lion of the day for the two last months; and anecdotes of him, his writings, his correspondence, his collection—the last fallen into the hands of that eminent anti-collector, alias *dispercer*, George Robins—have been retailed day after day. Such being the case, it may be imagined that there can now be very little indeed left for us to say upon the subject; but, strange as it is, it has actually happened that of the house itself and of the taste displayed in it, nothing whatever has been said, beyond a few meagre, vague, and fumbling remarks, and those chiefly borrowed ones.

The original house—which forms but a small portion of the present one—had nothing but its situation to recommend it, being little better than—indeed, hardly so good as—some modern "cottages," and containing only a few small and low rooms. To these Walpole first added two larger and loftier ones—the dining-room and library over it, on the north side—in 1753; and in 1760-1 extended the whole very considerably by the gallery and round tower, and tribune or cabinet, with the farther addition of the great or north bedchamber in 1770, six years after which he erected the small Beauclerk tower.

Horace may, therefore, be said to have "collected" his house as well as the curiosities and articles of *virtù* with which he stocked it; but though this piecemeal mode of building has been, perhaps, so far advantageous, that it may have prevented perfect uniformity of insipidity in the exterior, it has not prevented insipidity itself, nor has it produced any sort of character that can be termed picturesque. As to style, we meet with nothing at all better than either Batty-Langley-Gothic, or Guildhall-front Gothic—nothing whatever beyond the vulgar idea that mere pointed holes in a wall, and battlements on the top of it, are sufficient to constitute a Gothic edifice. We are ready to make allowance for the difficulties then attending any attempts in that style: at that period there were no publications in which it could be studied by means of accurately delineated forms and details; but if no such information was to be derived from books and engravings, most assuredly it was to be obtained from actual buildings, many of them at that time in a far more perfect state than at present, or even when drawings were first made of them. If he really possessed any feeling whatever for the art, it might be supposed that a man like Walpole must have derived some insight into the principles and genius of the pointed style, domestic as well as ecclesiastic, during his residence at Cambridge where he was the fellow-student of Gray—from whose taste he might have acquired something—and where he had constantly before his eyes examples which, if he had not sufficiently studied beforehand, he might at least have bethought himself of when he did set about building in a style not at all understood by professional men and their assistants.

Scott tells us that "the villa at Strawberry Hill gradually swelled into a *feudal castle*!" that Walpole "realized his own visions"; and that "in his model of a modern Gothic mansion, he had studiously endeavoured to fit to the purposes of modern convenience or luxury, the rich, varied, and complicated tracery and carving of the ancient cathedral"! Perhaps, recollecting the architectural sinings of the author of Abbotsford, Sir Walter thought that any reflections in a less indulgent tone upon those of the author of Otranto and Strawberry Hill, would come with a very bad grace from himself.* When, again, Sir Walter speaks very liberally and in pluralist phraseology of "turrets, towers, galleries, and corridors, with fretted roofs, carved panels and illuminated windows, &c.," "garnished with all the panoply of

chivalry;" wherein he certainly indulges not a little in the privilege of a romance writer, and somewhat trespasses upon that of the *flourishing* George Robins. To talk of the galleries and corridors of Strawberry Hill inevitably calls to mind the old story of the boy and thousand cats—with this difference, indeed, that the boy at last admitted there really were *two* cats, whereas it is impossible to make out more than *one* gallery at Strawberry Hill, and nothing whatever deserving the name of corridor, as the plan of the building—and there is no arguing against such evidence—plainly shows. As to Gothic tracery and carving, there is scarcely any, and most certainly no tracery to be traced in the windows, which are externally no better than so many gaps, without even any sort of mouldings or other finishing. Now, whatever errors there might have been as to combination and general character, it might have been thought that a man whose taste was so essentially *microscopic* as was Horace Walpole's would, at any rate, have been tolerably exact as to minutiae and detail. Yet, so far is this from being the case, that even those parts of the interior fittings-up which are said to be expressly in imitation of original models, retain very little of them except the mere general pattern, without aught of the original character; as it is, the bookcases are only "bird-cage" Gothic—most meagre and wiry. It is singular that one who could note all the most trifling details of workmanship, in minor articles of *virtù*—in carvings, enamels, ivories, bronzes, &c.—should be incapable of distinguishing the prodigious difference between his own *soi-disant* Gothicizings and the things they professed, however distantly, to imitate; or that if at all aware of such difference in what regards character and feeling, he should not at once have detected the cause of it, and adopted a more satisfactory system.

We do not, like many, make it a sneering reproach against Strawberry Hill, that it is little better than "a lath and plaster" fabric, patched together at different times. Neither of those circumstances at all affects the question now under consideration; for however light or even flimsy in regard to construction the house itself, it might have been made to display, as an architectural idea, many finished graces of design, well-selected and well-studied forms, well-understood profiles, careful and well-executed detail: there might, in short have been something like *gusto* manifested in the treatment of the subject, though the materials employed were ever so slight and homely. The employment of fictitious materials—of wood instead of stone—of ornaments and mouldings cast in composition or papier mâché, instead of being carved by hand, does not necessarily produce a trumperiness of appearance; on the contrary, whether the result be trumpery-looking or not depends less upon the worth of the materials and the mode in which the appearance aimed at is produced, than upon the taste which the architect or artist expresses in his ideas. Instead of beauty of design being destroyed by the ordinariness of the materials employed, it confers an æsthetic value upon these last which makes ample amends for their want of costliness; and if there is to be any disproportion at all between the worth of the one and the other, it is a lesser fault to have an artist-like design executed in "trumpery" materials, than a trumpery and tasteless design, however excellent the materials employed for it.*

Of both trumpery and bad taste, and of gross architectural solecisms—many of them downright vulgar in themselves, and almost inexplicable, as sanctioned by one who has the credit of having been a "minute antiquary"—Strawberry Hill affords so many instances, that wherever any sort of illusion is produced it is only for a moment, being dispelled at the next glance, or the next step. We grant that Walpole himself speaks very disparagingly of his own architectural doings, but it is with that sort of affected compliment-begging humility, which seeks nothing so much as to be contradicted; and

* The house at Abbotsford is so contemptible as an architectural production, that all the *prestige* attending the associations connected with its name vanish on beholding it. Most persons have been wotully disappointed in their expectations of it—some have even expressed their regret that they have seen it at all.

* Of course this is to be taken *cum grano salis*; we must not be understood as holding it to be matter of perfect indifference whether a building be solidly constructed or not, provided it does but satisfy the eye, because, in proportion as it is beautiful, is the pleasure it affords increased by knowing that it is durable also, and calculated to last indefinitely. What we chiefly mean to say is, that where any sort of character is aimed at at all, the slightness of the materials, or their being fictitious ones, is no excuse at all for the design itself being incorrect, slovenly, and tasteless.

though he is pleasant on the subject of his flimsy battlements, of which he says he had outlived three generations, he seems unconscious of the vulgar and cockney taste displayed in sticking up such paltry things at all. In point of taste, indeed, the exterior looks just such another sheepishly-fierce and frowning piece of "feudal castle" architecture as that box of battlements which has imposed upon no less learned an antiquary than John Britton himself, who—not having, perhaps, a prompter at his elbow at the moment—has pronounced it, in his publication on Edinburgh, to be—*beautiful*!

We will now proceed to examine the Strawberry Hill mansion more methodically and minutely. There is, indeed, one thing in its favour, namely, that neither externally nor internally does the entrance make any fallacious promise. So very far, indeed, is it from exciting expectations to be afterwards succeeded by disappointment, that it rather damps them altogether. You reach the entrance door through a little narrow alley, on one side of which are three paltry arches in the starvation-Gothic style, forming what is by courtesy termed a cloister, in which is—perhaps we should now say was—deposited a queer-looking piece of old crockery ware, which, you are told, was the identical china vase on which the "pensive Selina reclined," the feline female whose memory is embalmed in the stanzas of Gray. We almost wonder, therefore, that this cloister was not called the *Cat-acomb*, a title that might have been bestowed upon it with as much or more propriety than it is upon some of the passages and corners of the Soanean Museum. The mention of the last is, perhaps, somewhat unlucky, since it irresistibly leads us to remark that Soane and Walpole resembled each other in the architectural taste they displayed in their own houses, both of which seem as if put together from fragment, picked up at different times at some curiosity shop, and whose several parts, even to mere passages and closets, are dignified with fine names. If in the Soanean one we have the Monk's Parlour, the Monk's Garden, the Shakspeare Recess, the Catacombs, &c., in the other we have the Refectory, Armoury (a landing of the staircase), the Shrine the Cloister, the Abbot's Garden, and so forth; an admirable system for even a blue band box might thus be converted into a Bluebeard's Blue Closet. Let us, however, boldly make our escape from th temptation to say more upon that head. Let us, if we possibly can restrain our pen, and compel it to be less frisky. Just now we talked of being methodical: alas for promises! There is more madness in our method, we fear it will be thought, than method in our madness.

As cloister there was to be, it would have been better to have planned it so as to be of some real service, which it would have been, had it been extended and continued (from *e* in the plan, which indicates the situation of the entrance-door to the house in the ground plan below,) as far as the entrance from the road, nearer than which a carriage cannot come up to the house; for in that case a comfortable sheltered approach would have been formed the whole way, one also that would have contributed—at least, might easily have been made to contribute—very materially to architectural effect as well as convenience. Or, putting both positive effect and convenience out of the question, the present skulking appearance of the entrance, which hides itself, as it were, in a corner, would have been got rid of. Having passed the threshold, we see little to announce architectural character and style of any sort, until advancing a few paces and turning to the left, we perceive the staircase, and there behold Gothic run mad, and ugly quatre-foil holes for windows, than which nothing can be more unlike anything to be met with in the pointed style, except perhaps here and there in some very rude and uncouth examples. Such things are no better than caricaturing the style pretended to be adopted: ugly in themselves, they have not even the humble merit of being passable copies—well-intentioned, but bunglingly executed. The same may be said of the rest, and the whole is no better than a mere patching together of incoherent bits of design, the only consistency observable being that all is nearly alike paltry, insignificant, and mean in taste; and how the possessor of Cellini's bell could tolerate such rapid architectural stuff—such mockery of Gothic art—is to ourselves incomprehensible. Passing up a flight higher than the first landing, or that level with the other rooms shown in the plan, we reach a

broader one, extended by what is called the Armoury (A), but which may be said to form part of it, it being only a sort of lobby, divided from it merely by three open arches. Of the armour we speak not, but in regard to the Armoury itself, it does not call up visions of the days of feudalism and chivalry, but is likelier to put to flight any dreams about Otranto. The transition from warlike to literary stores is here sudden enough, for, taking leave of helmets and suits of mail, we find ourselves the next moment among books. The library (B) may be termed "a fayre and goodly chambre" as to size, yet ungodly or bad enough in all reason as to the taste shown in its fittings-up. The design of the bookcases is said to be taken from that of the stalls of old St. Paul's, and sure enough, they do look as if the pattern of them had been taken from some ill-drawn old engravings, so meagre and wiry is it in all its lines, so hard and harsh in all its forms. The chimney-piece is borrowed from a tomb in Westminster Abbey; and the window is borrowed from nothing, but rather looks as if it were itself the original model or type of veritable cockney or carpenter's Gothic. Of such superfluities and encumbrances as mullions and tracery—which only serve to keep out daylight, and were, therefore, quite in character during the dark ages—it is perfectly innocent. Still it is in the pointed style, because it forms a great pointed opening in the wall. Besides this window, there are two little quatre-foil ones over the bookcases at that end of the room, which at first sight have very much the appearance of being holes or gaps made by cannon shot. The ceiling is flat, and being painted all over with heraldic devices and compartments, looks very much as if it were covered with a Turkey carpet nailed to it. Surely our English Horace might have learnt both from his Roman namesake and from his brother peer Chesterfield, that paltry inconsistency is inexcusable in such matters; for if it is worth while to do them at all, it is worth while to do them well. Yet Walpole seems to have had no or little idea of architecture, beyond that of bringing in bits here and there piecemeal, just as if it was not at all necessary to observe any sort of keeping in the design of a room, but doors, windows, chimney-pieces, &c., might look as if they had been picked up at auctions, and afterwards patched up against the walls in the best manner they could. To say the truth, the old-curiosity-shop taste seems to have taken such strong hold of Walpole, that it predominated even in his notions of architecture; and we even suspect that his friend Bentley must have sneered aside occasionally, when he found into what strange sort of architectural companionship his chimney-piece compositions from tombs and Holbein gateways were brought.

This library, together with the "Refectory" or dining room beneath it on the ground floor, and of the same dimensions, were among the first made by Walpole to the old house; but although two of the largest among what may be called the sitting-rooms, they are both so detached from the others on the same floor, that they cannot at any time be made part of the general suite thrown open for company. We must, therefore, descend again, and passing through the small ante-room, C, called the Star-Chamber, from the pattern on its walls, reach the Holbein chamber, D, so named from its chimney-piece, one of Bentley's compositions above alluded to. In other respects there is nothing particularly Holbeinish in this room, or that confers upon it distinct character of any kind. Lady Morgan, indeed, says of it that it looks like a pet-room of Catherine of Arragon; but to us it looked rather like one exceedingly petty in taste, in which no attempt has been made to keep up with tolerable consistency any one style. Dividing off the alcove in which the bed is placed, is a screen of three pointed arches, the centre one left open, the others filled with perforated foliage—the whole altogether different in design from the chimney-piece and every thing else; and withal of rather too gimcrack and toyish appearance in itself. As to the "royal-looking bed" which Lady Morgan was so fortunate as to behold here, that must have since disappeared, for the one we lately saw struck us as being particularly mean, small, and shabby. Among the "sights" in this room was the Cardinal's hat, a most interesting relic no doubt, and perhaps quite as authentic as some of the highly prized and carefully treasured-up rags of the Virgin Mary's gown; in short one of those

curiosities which it is curious that any man of sense should think of giving house-room to, except in a lumber garret. Returning into the little passage, *p*, we advance to the right and turn into the gallery, which certainly comes upon us quite unexpectedly, and is all the more striking by contrast with what has just been passed through. So far this is exceedingly well contrived, though the credit of it ought rather, perhaps, to be attributed to accident and necessity: here we have not the anticlimax of a spacious gallery, presenting itself to view before any of the other rooms, and thereby causing them to disappoint us, as not keeping the promise made by the approach to them. Here the fault lies rather on the quite contrary side, there being no tolerably decent approach to the gallery itself, which cannot be reached at all, except through a very confined and poking passage, that has a sort of suspicious look about it, for it looks as if it led to some very private closet to be visited only on occasions of necessity. We should therefore like to be allowed to poke about and pull about here a little—to widen it by taking about three feet out of the adjoining chamber, and extend it by taking in the space marked *r* in the plan, and converting that addition into a shrine-like recess, viewed through an open arch or screen where the window now is, and lighted above through a concealed window of merely coloured or Claude-tinted glass, so as to diffuse a rich mellowing glow over the whole recess, which would thus become a miniature cabinet, wherein many articles of *virtù* might not only be deposited but displayed to very great effect. What is now a very awkward and paltry passage, considering where it leads to, might thus easily be rendered a very striking *passage*—an attractive *episode* in the general architectural composition and plan—a highly pictorial bit, because at all events there would be a powerful effect of concentrated light opposed to the dim obscurity of the rest. On entering such architectural corridor, we should behold a *picture* before us, inviting onwards, and distinctly enough announcing that we might expect something of more or less importance beyond it. Neither would such corridor or lesser gallery at all interfere with or diminish the impression made on first entering the larger gallery. On the contrary, there would still be quite enough of contrast, without any of that harsh and offensive discord that now rather disturbs our impressions, the plan being now completely dislocated, as it were, and its parts scattered from each other, without any proper connecting links, uniting them into one series. Were our pen a magician's wand, we should here work many transformations with it.

The Gallery, sometimes called, we know not why, the Great Gallery, there being no other, and its dimensions being only 56 by 15 ft., and 19 high, does certainly take us by surprise, and may be called spacious, in comparison with those parts of the house which precede it. It certainly manifests considerable improvement in Walpole's interior architecture. Its groined ceiling, in imitation of that of the side-aisles of Henry's VII's chapel, and of which the mouldings are gilt, gives a certain air of richness to the whole apartment; but most unfortunately, and perversely also, it is greatly marred by the five pendant and projecting canopies to the compartments and recesses on the side facing the windows, while there are no corresponding ones on the other, though they might there have had window draperies attached to them. Thus, instead of that degree of symmetry being attempted to be kept up between the opposite sides which is looked for almost as a matter of course in a gallery, it is here altogether destroyed, a defect that most assuredly is not at all helped by the extreme shallowness of the windows, which, instead of forming embrasures, are merely let into the wall a few inches deep, and consequently contrast very offensively with the recesses on the opposite wall. Therefore, taking our wand, we should take the liberty of transforming these into semi-hexagonal bays, of the same size as the larger recesses, or if not all five, at least the three middle ones. This would certainly be an improvement internally, and externally the throwing out such bays could not be an alteration for the worse, the outside of the building being already so detestably bad, that making it worse is almost next to an impossibility. We would also conjure up a door, or rather the vision of one, at the east end of the gallery; that is, a sham door with panels filled with looking-glass, so as to give an appearance of greater

extent, and form a feature at that end of the room corresponding with the door at the other, but would have both in better design and taste than the present one. In fact, nearly all the present fittings-up requires correction, and to be brought into harmony, for want of which there is now too much of the "scrap-book" character.

Lady Morgan speaks of the "Round Room which leads to the *sanctum sanctorum* of the edifice, the Tribune," but, as the plan very plainly shows, there is no such room between the Tribune (G) and the Gallery; and the Round Drawing-room (F) leads nowhere. This last is to us by far the most pleasing and unexceptionable room in the whole house: it has an air of simple elegance, comfort, and cheerfulness, with a quiet effect of light and shade. Yet even here there is one very sad fault—capable, however, of being easily corrected—namely, the pointed-arch door. Not only is such form inconvenient for room doors, but here more especially, because upon a curved surface; and so far from such acute form being required in order to accord with the rest of the design, it is positively at variance with it, the bay window not being arched at all, and the ceiling being *flat*; and as if with the intention of adding inconsistency to inconsistency, this door is painted *white*, with trumpery gilt mouldings. A *white door* is, as Goëthe says, at the best a solecism in taste; but in Gothic, or any style of old English architecture, quite intolerable, and one would as soon think of painting a fine timber open roof of that colour. In consequence of its being so painted, the door here produces a glaring spot, and the ugliness of its design is rendered all the more conspicuous.

As we do not pretend to speak of the contents of any of the rooms, of the Tribune we shall say very little. It is far better in its plan and general form as to section, than in its details and the style of its fittings-up. As to the north or great Bedchamber (H), there is nothing in it that calls for architectural remark at all. One thing, however, to which we would call attention, as a happy point or accident in the plan, is the vista obtained from the same spot at the upper end of the gallery—northwards into the Tribune, and in the other direction into the Drawing-room and its bay. Thus that room, the Tribune, and the Gallery itself, form a charming and pleasingly diversified architectural group; one so fraught with scenic effect, that, however much there may be to condemn elsewhere, there here is something worth studying at Strawberry. Therefore, ere we cool upon this compliment, we will dismiss our pen at once—as, in fact, it is time to do; merely adding, by way of epilogue or moral, that there is a far greater curiosity than any in the whole collection, or than the whole collection itself, namely, the highly curious circumstance, that after being assembled by one W, it should be scattered by another W; and that it should have passed from the witty, *virtù*-loving Walpole to the witless and vulgar-minded Waldegrave.

ARTESIAN WELL IN LONDON.—The sinking of the Artesian well in Piccadilly has, we believe, been attended with the most perfect success, and there is now every probability of an inexhaustible supply of the purest water. After boring to a depth of 240 feet water was arrived at, which immediately rose to within 80 feet from the surface. Over the well a handsome iron pump is in progress of erection, and the inhabitants may now reckon upon a certain and plentiful supply of fine spring water. The expense of this useful work is estimated at 600*l*. Such has been the success of the undertaking, and so many the advantages, that it is said to be in contemplation to carry out the plan in St. George's parish, by causing Artesian wells to be sunk in different localities, best calculated to contribute to the convenience of the parishioners.

THE ANTIQUITIES OF NEW SPAIN.

MUCH has been said and written, from the age of Herodotus to the present time, on the magnificent edifices of the ancient Egyptians; there is an undying interest felt about that people and their works, an interest we all feel, and one that will endure for ages; but in giving so much of our attention to this subject, interesting as it undoubtedly is, may we not neglect others which, if not equally, may be well worthy our attention and research. Such a subject, we think, may be found for us in the architectural remains of the ancient inhabitants of the Spanish Mexican settlements; but in pursuing it, it is not our present purpose to enter into the question, what race of men were the real executors of these remains: such a question would lead us far beyond the limits of our article, and as such great names differ in opinion on the subject, it will appear like presumption in us to decide the point.

Of the early inhabitants of New Spain the Toltecs are the most ancient nation of whom we know anything; they came from the northward, being expelled from their own country (supposed to be Tollan) about the year 472. In rather more than 100 years after this they reached Mexico, where they settled; but some time after almost the whole nation was destroyed by famine and pestilence, occasioned by extreme drought, and the remnant of the Toltecs was incorporated with the Chichimecas, a succeeding nation under Zoloth, one of their princes. There is considerable uncertainty as to the origin of the present Mexican race; according to Bolunni they left their own country (Aztlán, supposed to be an Asiatic province) about the year 1160, but did not reach Mexico until nearly 60 years after; there they were first subject to, and afterwards conquerors of, the ancient Toltec nation. For the sake of brevity, then, let us adopt the name of Toltec for the architectural works we speak of, although the present natives attribute the erection of the buildings to "a race of giants," (a name given by many ancient nations to the Pelasgi), and proceed at once, as far as lies in our power, to the description of the works themselves, as it is plain that to whatever nation they owed their origin, they (the nation) must have had considerable general knowledge, especially of the mechanical, geometrical, and astronomical sciences.

The general form of the Toltec religious edifices, and indeed the guiding principle in all their works, seems to have been the pyramidal, but unlike the pyramids of Egypt, they were not merely sepulchral monuments, but temples in themselves. Instead of their being graduated in regular courses, they formed stages or towers, each tower being a truncated pyramid, rising one above the other to the height of several stages, the upper surface of each tower (being flat) forming a base for and terrace surrounding the tower immediately above it. These buildings were square in plan, and the sides faced the cardinal points. The sanctuary was situated on the topmost tower, and it is a very singular coincidence that this kind of temple, the one at Cholula especially, answers almost exactly to the description given by Herodotus (Clio) of the temple of Jupiter Belus. He says "It is a square building. In the midst a tower rises, upon which, resting as a base, seven other towers are built in regular succession. The ascent is on the outside, which, winding from the ground, is continued to the highest tower. In the last tower is the holy place (*naos*). As it is generally supposed, from various circumstances, that the Toltec temples were dedicated to some solar divinity, the coincidence is the more remarkable, as the sun was worshipped under the name of Baal or Belus by the various nations of antiquity. The ascent to the place of sacrifice or sanctum sanctorum was by means of a broad and well finished flight of steps, usually situated on the western face of the temple. Sometimes this staircase, instead of ascending in a direct line, as in the flower temple of Xoichicalco and others, traversed each tower in a diagonal or zig-zag course from the lower to the upper angle, as in the temple of Cholula before mentioned, and occasionally there were four flights, one on each face of the building; the temple of Tehuantepec may be quoted as an example of this last, but in it the principal staircase faced the west. It may be as well to mention

that at Cholula, Dupaix discovered a very fine stone head, having on a kind of crown; from various circumstances he considered it to be either the capital of a column or part of a caryatic figure. The sides of their pyramids were sometimes ornamented with stone heads, but they were of quite a different description, more resembling the human skull. This was perhaps in allusion to their religious services, as it is well known they sacrificed human victims upon their altars. At Xoichicalco (House of Flowers), the great temple has its sides adorned with immense flowers cut after erection; Nebel has restored this building in his work. To give some idea of the magnificent scale upon which the Toltecs executed their architectural works, it will be only necessary for us to give the dimensions of the great pyramid of Cholula. As nearly as can be ascertained (for the angles of it are much worn) its base is upwards of 1400 feet square, or rather more than twice the size of the pyramid of Gizeh, although in height (from the width of its terraces) it does not exceed 180 feet.

There has been much discussion among the moderns as to what style was adopted by the architects of Solomon's temple; some have supposed it to have been the Grecian Doric, others (ourselves among the number) have considered it the Egyptian, but Lord Kingsborough has brought a more novel theory into the field. He considers the Toltec remains were executed by a portion of the Jewish nation settled in Mexico, and the Toltec temple of Palenque to be modelled by them after that of Solomon. The general plan of this building is square; it is raised on a low truncated pyramid as a basement, and the ascent to the level of the floor is by a broad staircase situated on the eastern side of the temple. A kind of double gallery runs round and partly across the building, and divides it into three areas or open courts. The galleries, as well as the other chambers, have roofs rising high like the Gothic; the ceilings of the interior are similar, with the exception of their section being a truncated triangle. Out of one of the courts rises a square tower of very good proportion, diminishing gradually, of several stories in height, and having on the inside a staircase running up to the top. This tower was probably used by the Toltecs for an observatory, as we know they studied astronomy, not only from their manner of placing their temples, &c., but from there being some of their zodiacal carvings still extant.

At Mitlan are ruins of four buildings called "the Palaces," (Dupaix thinks they are sepulchral monuments and not the abode of their kings) the design of which seems to indicate the existence of a purer and more refined taste in their architect than is exhibited in most of the other Toltec works. It is difficult to convey an idea of the plan of all these erections by description only, but we will take the principal one as the best suited to our purpose. Four buildings surround a square or court, three of them are rectangular parallelograms in plan, each containing one saloon; the fourth is similar to the other three, but has, in addition to the saloon, some chambers behind it, forming altogether a plan much resembling the Egyptian Tau. The greater part of the exterior is covered with elaborate and exceedingly beautiful designs in Mosaic, some of them vary much in the style of the Greek meander or fret ornament; the same mosaics are used on the architrave of the interior. In the saloon of the principal building are six granite columns without base or capital, supporting the ceiling beams; these are almost the only columnar examples we find, as the Toltecs generally made use of piers or substantial antæ in lieu of them. The walls were constructed of well tempered mud, lime and sand, the large stone facings being pressed into them to a certain depth while in a soft state, and the interior of the work was finished with a fine hard stucco bearing an excellent polish, and painted with ochre and vermilion. It is a circumstance worthy of notice that although chisels and other instruments of copper have been found among the Mexican ruins, no iron ones have ever been discovered. How then did the masons square their stones for building? (it is evident copper tools would not have been sufficiently hard for the purpose). Dupaix thinks they squared them by means of friction, and his opinion may receive some confirmation from the fact of their surface being exceedingly smooth. Under the saloon of the palace is a cruciform sepulchral chamber, entered by a flight of steps from the court above.

The ceiling of it is formed by beams of stone laid transversely; but at the intersection of the cross is a cylindrical column supporting a square slab of stone or abacus, forming the ceiling of the chamber at that part. The interior is richly ornamented with different kinds of mosaic fret, and is painted with vermilion. If we may judge from the ruins of their sepulchres which still exist, the Toltecan nation must have paid the greatest respect to the memory of their dead. Occasionally we find them deposited in caverns wrought by hand, similar to the one we have just spoken of; there is likewise one of the same cruciform shape at Chilan, and another, containing three chambers, near Xochicalco; but most commonly they constructed a large conical heap or tumulus, and faced it with stone or brick; through this was made an arched passage usually running north and south. A tumulus of this kind at Mount Alvan has one side of this passage lined with oblong slabs of granite carved with human figures. There is a very remarkable sepulchral monument situated likewise at Mount Alvan; it is constructed in a conical hill like those before mentioned, but there is also an arched passage running east and west, intersecting that running from north to south. At this intersection is a large and well constructed rotunda, the dome of which is somewhat in the shape of a parabolic conoid; the sides and interior are lined with good masonry, and at the top is a kind of funnel or chimney going right through to the exterior summit of the tumulus; this was probably used for purposes of ventilation.

The Toltecan generally made the arches of their bridges square headed, by means of a stone lintel laid across from pier to pier, but not unfrequently they placed long beams of stone leaning towards one another at an angle of about 55 degrees, and meeting at top, forming a kind of triangular straight-sided arch. In the province of Thascala are the ruins of two bridges of this latter description, and the angles of the roadway are ornamented with four piers or obelisks, of about 50 ft. in height, having an imposing effect. There still exists at Chilhuittan a bridge very peculiarly constructed by means of large blocks of stone, the upper surfaces of them being cut convex and the lower concave, springing from their piers and meeting together at the crown of the archway. The arch thus formed bears a great resemblance to our Gothic "Lancet."

Perhaps it may be as well to say something of the roofs, doors, and windows of the edifices we have been describing. Of the first the interior frame was in most instances triangular, the angle at the apex being rather acute; but there are examples in the form of an inverted cyma, somewhat like the roofs of the Chinese buildings. Internally the sections of the ceilings were sometimes plain-sided triangles (occasionally truncated), at others they were graduated in overhanging courses, forming a kind of arch. The doorways were of a square or oblong form, having merely a plain stone lintel resting on its piers. Very many of the windows and niches are of the same description, but we find in them a much greater variety of form. They are some of them arched at top, some triangular, some in the shape of the Egyptian Tau, while others resemble the trefoil-headed Gothic arch.

e

PROTECTION OF LAND AGAINST THE SEA.

THE expedient about to be described was put into practice at a part of the Moray Firth, near the town of Inverness, North Britain.

There was great reason for supposing that the Firth had encroached enormously at this place; and so certain and rapid seemed its progress towards the destruction of a portion of the carse land known by the name of the "Longman," lying between it and the rich town lands immediately contiguous to Inverness, that the inhabitants, foreseeing the certain destruction which awaited the town lands, and perhaps ultimately the town itself, if the carse land, which had by this time been reduced to an average breadth of about 100 yards, were not protected, determined upon erecting a very substantial wall, (A) as represented in the annexed sketch, and it was hoped that the evil

would be thereby effectually cured; but after resisting the action of the water for some years by the aid of almost constant repairs, it was at length so much damaged that proposals and estimates were submitted for the purpose of erecting another wall of much stronger dimensions, and the inhabitants were preparing for another serious demand upon their purses, when they were agreeably surprised by receiving a proposal from Mr. William Hughes, then a contractor upon the Caledonian Canal, to protect the town lands effectually, and that at no cost whatever to the town, as he required no farther remuneration than the possession of the stones of which the wall had been formed. This agreement was eagerly entered into on both sides, and both parties were perfectly satisfied with the result.

The contractor's mode of operation was extremely simple, as may be seen by the sketch: the beach ascended from low to high water-mark at an inclination of about 1 in 9, and then rose abruptly about 3 ft. to the level of the carse lands. Having removed the old wall, the contractor considered that nothing more was wanting than the formation of a beach of sufficient solidity to resist the action of the water, and having at the same time such a section as to allow the waves to exhaust themselves without meeting with any substance which might be injured by them. These objects were attained by removing sufficient stuff to admit of the beach being carried up and terminated by a gentle curve tangent to the original beach, whilst the surface of this newly-formed beach, and also down towards low water-mark, was rendered solid by excavating a foot in depth, and depositing therein boulders found on the beach. This formation is represented by B in the sketch; and we have only further to add that nothing could have proved more creditable to the contractor, or more serviceable to those interested in its success, since, from the time of its completion till the present time, a period of not less than 26 years, the town has not lost one foot of land, nor been put to any expense for repairs.

H.

NOTES ON EARTH WORK, EXCAVATION, CUTTING, AND FORMING EMBANKMENT UPON RAILWAYS.

ARTICLE II.—PLANT, HAULAGE, AND CONTINGENCIES.

"Modern practice has reduced it to a price per cubic yard."

Professor Vignoles' Lecture, Dec. 1841.

THE rails, wagons, sleepers, &c. used by contractors, are called the "Plant," and are of a lighter description than those used for permanent works. The rails range generally from 26½ to 30 lb. per yard, and the joint pedestals or chairs 20 lb., and intermediate chairs 12½ lb. each. The following were the prices paid in 1837:—rails 13l. per ton; chairs 9l. 10s. per ton; keys 24s. per cwt.; sleepers 1s. to 1s. 3d. each. The plant required for the conveyance of 213,000 cubic yards of earth with embankment consisted of 157 tons of rails, 67 tons of chairs, 28 cwt. of wedges and nails, and 42 wagons, estimated to contain or carry 1½ cubic yards each, costing 18l. 10s. each,* and 96 to contain 2½ cubic yards each, costing 23l. each. The cost

* Wagons to contain 1½ cubic yards of earth, of which 42 were used—cost £777.

1 set of wrought iron work pedestals, bolts, and hoops, 390 lb.	£.	s.	d.
at 4s.	6	10	0
1 set of 24-in. wheels and axles	7	15	0
19 cubic ft. of elm, at 3s.	2	17	0
Labour of making each	1	8	0

18 10 0

Wagons to contain 2½ cubic yards, of which 96 were used, each 23l.—cost £2208.

of repairs for each wagon was from 1s. 3d. to 1s. 6d. per week, no less than 97 out of 103 wagons requiring extensive repairs in one month. In addition to the repair, the lubrication or greasing of the wagon is a considerable item of expense. Supposing the plant sold after the completion of the work, it would perhaps produce—rails 8l. per ton; chairs in proportion; large wagons 13l.; small wagons 11l.; and sleepers 9d. each.

From all I can learn, and judging from my own experience, I calculate that the cost on each work for rails is about 1½d. per cubic yard, and for wagons 1d.†

Before I proceed to consider the cost of haulage or horsing, I will give what Mr. Day says on the subject, in his Treatise on Railways, although not in his exact words:—"Taking resistance at 150th part of insistent weight for temporary roads, and horse power at 150 lb., to travel 12 miles loaded and 12 with empty carriages, at the rate of 2½ miles per hour, and allowing a fourth for weight of wagons, a horse will convey 64½ cubic yards one mile per day, which, at 7s. per day, including attendance, is equal to 1½d. per cubic yard; and that the effect of ascending a gradient of 35 ft. per mile will double the cost, 74 ft. treble, and 105 ft. quadruple it."—The cost is not in the ratio of the relative distance, as the haulage to and from the tip and gullet apply as well to short as to long distances. For the first mile I do not think that 2½d. per yard is too much for haulage, which is nearly double Mr. Day's estimate.* I consider that horse power is preferable to either fixed or locomotive engines, when the lead is under 2½ miles, but up to 4 miles a locomotive is to be preferred; and when the lead exceeds that distance, it will be cheaper to purchase land for side cutting, and run the surplus to spoil at the commencement of the cutting, or run the top lift into the adjoining fields. The average lead for most of the railways already made seldom exceeds one mile, which has been taken as the standard measure of cost, for which the price is generally about 1s. per cubic yard for the first mile, and 3d. per mile additional, or 1½d. per half mile, beyond the first mile.

The following are the prices at which many contracts have been executed

† On account of the capital required for plant being so great, it is sometimes the custom for the companies to find rails and wagons, the permanent rails being allowed to be used for temporary purposes. The value of a plant for a contract 5½ miles in length, to convey 213,000 cubic yards, is nearly one-third of the amount of contract, taking 12d. per cubic yard as the price, viz. for—	
Rails, chairs, keys, &c.	£3300
Sleepers	300
Wagons	2985

Total 6585

About seven miles of rails were used, besides two miles of wooden rails plated with iron for a back road, on which only the empty wagons passed. The facility afforded in tipping fully warranted this quantity of plant. The usual calculation for the quantity of rails required is the length of contract undertaken, if the works are to be carried on with vigour.

* Horses' keep calculated at the above:—

1 load of hay, 36 trusses of 56 lb. each, at 105s. to 110s. per load.
1 load of corn, beans, or oats, 5 qrs. and 8 bushels 1 qr. at 30s. per qr., and weighing 37 to 43 lb. per bushel net, allowing 3 lb. for the weight of the sack; beans, whole 2 cwt. 1 qr. 12 lb. per sack, split 1 cwt. 2 qr. 3 lb.; oats 1 cwt. 1 qr. per sack, at 25s. per qr.

Keep of horses at the above price, exclusive of driving.	
per week each.	per day each.
136½ lb. of hay	19½ lb. of hay
94 of oats	13½ of oats
23 of beans	3½ of beans
17s.	2s. 5d.

30 horses in 12 weeks consumed

740 bushels of oats,

180 ditto of beans,

181 trusses of hay.

42 horses in one week consumed

69 bushels of oats,
51 ditto of beans,
32 trusses of hay,
3 sacks of bran.

35 horses in one week consumed
70 bushels of oats,
42 ditto of beans,
24 trusses of hay.

20 horses consumed in one week
35 bushels of oats,
21 ditto of beans,
2 sacks of bran.

The cost of harness is 2s. per week each.

Repairs of ditto and shoeing 6d.

Farriery and medicine 6d. per week each.

The value of the dung pays for the straw.

35 horses took 2250 cubic yards	67½ chairs at 3½d.
55 " 2868 "	72 " 4½
55 " 3600 "	82 " 4½
55 " 2900 "	102 " 4½

on some of the great lines:—Midland Counties 12d. and 3d. per additional mile; Derby and Birmingham 12½d. all through average of lead; Great Western 12d. and 3d., and for ballast 1s. 5½d., and 6d. per additional mile, (on account of the difference in weight, say 19 cwt. to 28 cwt., between soil and wet gravel). On the Newcastle and North Shields Railway the price was 13d., which I have divided as follows—excavations and repairs of wagons 8d.; rails and wagons 2d.; horsing 3d. From the above prices I think I may say that the price per cubic yard may be set at 12d., which may be divided into the following items:—

Getting and filling	4½d.
Ganger's superintendence	½
Repairs of temporary road	½
Tipping	¼
Plant, wagons, and rails	2½
Horsing	2½
Contingencies and profit	1½
	12

In addition to the price of 4½d. for getting and filling, 3d. extra must be added, if it should be necessary to resort to *gulleting* for the greater facility of execution. It frequently happens that the earth to form approaches to bridges is taken from the small severances of land in the immediate vicinity of the bridge, and the earth moved nearly vertically, by the employment of what are called "horse runs," the excavator, with his loaded barrow, being drawn up a slope of planks laid often at an angle of more than 45°. The price for getting the earth in this case is generally estimated at 1d. per man in the hole, only one man being employed as runner, the distance from the foot of the slope requiring more or less men, as the case may be. In the preceding observations I have considered the prices of earthwork, barrow work, run work, and wagon work. The parts I have not touched upon are horse work, meaning cartage, and tram work, and when tubs are used put or pushed by men—this information probably some of your correspondents, who may have the data, will supply.

When it is considered in what a hurried manner contracts are let, the contractor in the space of a few days having to satisfy himself of the nature of the strata and the correctness of the levels, also the quantity, which has perhaps occupied the engineer and his staff months to ascertain; also the arbitrary manner in which the conditions are framed, his materials liable to be taken from him, and his work entered upon by the company at the mere dictum of an engineer, it is surprising that men are to be found of energy sufficient to risk their capital for such a small chance of profit. And besides, such contingencies as wet and frosty weather, rise of wages and materials, and the risk of errors in calculation, both as regards clerical errors and errors in the principle, whether the prismoidal formula or average depth be employed in the calculation.*

Professor Vignoles, in his sixth lecture (*Journal*, p. 60), says that the correct method is by the prismoidal formula, and that in a quantity of 332,000 cubic yards so calculated, and by average heights, there would be a difference of 22,000 cubic yards against the contractor, and if the mean area be used, there would be an excess of 44,000 cubic yards in favour of the contractor; hence, by the latter many contractors had realized, and by the former many had lost large amounts.

It is to the industry, energy, and boldness of the English contractor that enables him to carry on such extensive works as are undertaken in this country, and has thrown the Continental railways into his hands; and he has reason to be proud of the distinction. It is a practical illustration of the maxim that science is blind and without hands, and useless unless guided by experience. Many of the contracts on the English railways have been in the hands of men who could not write their own names.

I did not, when I commenced this paper, intend saying anything of the comparative cost of excavating materials of a more obdurate nature, but to confine myself to common earth; but from the interest I have taken in the

* There are also to be added the risk of an error in the fixing the value of the average lead, which I think is the most important point of all, requiring the exercise of the soundest judgment. And again, it seldom happens but what the rate of the gradient varies in the length of a contract, which will make a great difference, as before stated, a rise of 35 ft. per mile will double the price of haulage, and to have a small descent with the load is as greatly in favour of the contractor. There are besides the slips in cutting, and subsiding in embankment, and the upholding of tunnels, and other hazardous work; and as if all these contingencies were not enough, one of the principal engineers, lately in his report to the directors, urged the propriety of including in the contract for work the value of the land required for the railway.

subject, I am induced to add a few words. Perhaps by so doing I may elicit some further information from some correspondent, who may have the means of continuing the subject on rock excavation and blasting. In the first place I will give what Mr. Booth, of the Liverpool and Manchester Railway, says in his pamphlet on the progressive operations of that undertaking. The excavation was about 2,006,000 cubic yards: it was removed from a few furlongs to between three and four miles in length. The excavations at—

General price per cubic yard.

	s.	d.	s.	d.
Edge Hill; red sandstone	1	6		
Olive Mount; red marl and sandstone, two miles long	1	0	2	0
Rainhill; clay, marl, and sandstone	0	8	1	1
Kenyon; sand, gravel, and marl	0	8	1	0
Eccles; marl and sandstone	0	10	1	4

It is unfortunate that the general price only is stated, which I suppose to mean an average lead, and not the standard of per mile.

On the Great Western Railway, near Keynsham, the cutting through limestone cost 10d., 1s. 3d., 2s. 5d., and 2s. 6d.; but this again was general, the standard for comparison being wanting, or the horsing being mixed with the getting. On the Cromford and High Peak line, through limestone, the excavation cost 10d., also an average of lead. If I may be allowed to hazard an opinion, I think the price of common rock would be for getting only 10d. to 1s. On the Glasgow and Paisley line, at Bishopton, the most expensive I ever heard of was through drifting whin or greenstone. It cost 6s. per yard; it was harder even than granite; and in the Bishopton excavation alone 621 tons of gunpowder was used. I have known tunnel work through gypsum and marl cost 2s. per yard for labour only, without risk of water.

Rates of tonnage per ton per mile:—

Stockton and Darlington Railway—Coals and cinders, 2½d per ton.

Cromford and High Peak—coal and coke, 1½d. per ton.

Brandling Junction Railway—Slate and tiles, 4½d. per ton per mile.

Great North of England Railway—timber, 1½d. per ton per mile.

Hartlepool Railway—coals, 1½d. per ton per mile.

St. Ann's, Newcastle-upon-Tyne.

O. T.

ON FRESCO-PAINTING.

By JOSEPH SEVERN, OF ROME.

(Continued from page 165.)

In my former remarks (see *ante*, p. 161.) I attempted to explain why English artists would be more likely to excel in the grandeur of historical painting, through the medium of the fresco, rather than the oil material, and that the obstacles were not in our ignorance of that simple medium, but in our defective design, including our artificial and theatrical notions of composition. I hope now to be able to show, that in those essential points, design and composition, the English school possesses the real groundwork, which, with singular injustice to itself, it rarely or never exercises to its full extent, and which, if it did, there would be a hope of our surpassing all the continental schools of art; as I think the rare quality, which I am about to explain, is not to be found in so high a degree (if it is to be found at all) in any of them.

Judging the art of painting, as I do, by its great Italian examples, particularly in fresco, which is its province of freedom and power, I should say that there is a real and individual groundwork applicable and belonging to all the various powers of painting. This groundwork is Nature; not the perfect nature applicable to sculpture, often mistaken, and much abused in our time, as one and the same—but nature, with more of her imperfections than is generally supposed; imperfections that are essential to painting, if character and expression, or in a word *life* be the object. No doubt sculpture, and the beautiful antique figures particularly, have somewhat blinded us as regards painting; and I cannot but think, that if it were the good fortune of modern times to turn up an antique picture of high Grecian art, even by Apelles or Zeuxis, we should find it entirely different to their sculpture in design and composition, as well as in everything else, for such is the case in the inferior examples at Pompeii and Herculaneum, wherein the principles I am anxious to explain are always found.

Sculpture exists in the perfection of form, whatever that form may be, and it must be selected from various examples; for it is rare indeed to find perfect form in one individual model, as adapted to sculpture; and this can be easily understood when it is considered, that sculpture presents nothing but

abstract form to the eye. But painting, on the contrary, imitates nature in all her infinite variety; and in this universal imitation an obvious distinction is to be made, not only as to the means of the art, but the mode by which the painter attains his object. Historical painting, in including the diversities of complexions and customs of the people of different nations and ages, is obliged to include much that is ugly and unseemly, as well as much that is imperfect in form; for the painting art rests on its powers of representing character and expression with all the life and vigour it is capable of; and forms and things which would be vulgar, mean, and even incompatible with the abstract and limited power of sculpture, are obliged to be taken with all their imperfections by the painter, for they assist the pictorial and mental powers of his art. I am induced to dwell on this nice distinction, because, with reference to fresco-painting, I know that many persons suppose that the "good drawing," talked of as necessary, means the sculptural perfection of form I have been speaking of, and which, as applied to painting, carries with it the impression of insipidity and weakness, and seems to exclude the representation of vigorous character and living expression, which most of us feel to belong to painting. But sculpture, and sculptural perfection, as applied indiscriminately to painting, has helped to tame it down to a classic imbecility, if I may so call it, where the spirit of expression is driven to dwell in the extravagance and unnaturalness of academical and theatrical attitudes. When character and expression are not allowed to exist in form, then there is nothing left for them but attitude. This, I conceive, will explain at once the vast difference which is manifest between the quiet and natural manner in which the great Italian painters represented history, and that of the modern French, who have attempted to affect us in their historical painting by every species of action and extravagance, though always with the perfect forms and the drawing of sculpture. Their theory was to give perfection to painting, by imitating the perfection of antique sculpture; and they succeeded in introducing an original style, but from which we turn with displeasure, and sometimes disgust, to dwell on the repose and simplicity of the Italian masters, who, although accused of every kind of defect, we return to, and love even for their defects, because they are natural, and because painting assumes to be the universal language of nature. The French, in imitating the antique, have thought it expedient to give Apollo forms, more or less, to all their figures—to pare away every imperfection of humanity, whether it be in gods or heroes, or even in common men; and hence they have excluded character and expression, save in violence of attitude. This is the sad change which many English people falsely anticipate is to be brought about by fresco-painting; and this is the mistake which I am anxious to correct, in advocating the cause of fresco-painting.

Who will be so bold as to say, that perfect and select form is essential to painting, when, in the finest examples of Raffaello, Domenichino, and all the other great Italians, we find in every figure some example of the imperfections of nature *purposely* introduced—I say purposely, as there is no other rational way of accounting for the fact, but that they did it on principle. The antique figures were before their eyes, even more vividly than they are before ours: they were dug up in their time, and must have appeared more wonderful from their novelty; consequently, the Italian painters must have had the same temptation to take or leave them as we have, and they *did* take them, but *in part only*, and so far as they helped to develop the true and distinctive characters of painting. The French take them entire, and the English never take them at all. We can find, for example, in the figure of Heliodorus, by Raffaello, something of the grand form of the Illissus (in the Elgin marbles), but we find nothing of the antique in the terrible scourging angels, who strike him down with such energy and life. Now, who can say that if the imperfection of forms which are found in those angels were taken away, it would not leave somewhat of tameness and insipidity? or why, if we are struck by the terrible fury which Raffaello has given these figures, should we not infer that it exists even in the ruggedness of their forms?

I can well remember the shame and surprise I felt on first going to draw in a foreign academy, at Rome—where every artist, even the beginners, produced such beautiful forms. But the fascination was soon dispelled; for week after week different models of different ages and characters were brought before us, from the young and gentle, to the strong and muscular, and these artists I found made them *all alike*. The different characters were so refined and idealised, that it seemed to me I was no longer in the province of Painting, but in the ideal world of Sculpture. Young as I was, I might blindly have concluded that these artists were in the right, had there not been all those immortal fresco works around me with which Rome abounds, and which convinced me of the modern error, and in the inspiration of which works I venture humbly to offer these explanations.

These works will show that the Italian masters selected individual nature—no doubt the finest examples, but always individuals. How, indeed, is it possible to give that character which the art demands, without individual nature, whereon to raise that structure of life and energy, that endless variety of forms and colours, those varied costumes with all their particularities? Again, look to the landscape and architecture, with those effects of atmosphere which give such reality to the historic scene—how is it possible to make the figures belong to these (and to these they must belong), if the forms are to be perfected with so much ideal beauty that they become the only unnatural things in the picture?

Painting will have men nearly as they are; give them mind to any extent, give them overflowings of life and soul—but they must look like men, for the art will have it so, as it had it in all the great Italian examples. Let sculptors revel in their ideal world, but we must live in a real one if we wish to be painters. This brings me to the immediate point of my subject, without which these remarks would be impertinent—the groundwork of design existing in the English school, but only the groundwork. This I consider to be rather in the charm of nature as a characteristic, than in the mere artistical power of drawing academically well; for the one may exist without the other, but in the design I am explaining they must exist together. Its grand principle is in the natural, correct, and graceful building up of the figure. Reynolds is great in this, although he is thought to be so bad a draftsman, while thousands of inferior artists succeed in the academical part; all France and Italy, indeed, abound with them; in the latter country, even children learn to draw according to the trick before they learn to read or write. Reynolds aimed at something higher. It is true he gives us slovenly and ill-defined extremities, (the result, not of ignorance, but of his numerous experiments) but he *never* gives us a figure ill built up, or without the irresistible charm of nature; and this I find, more or less, the characteristic of the English school, in contrast to every other. It may have defects in the details of its drawing, it may have unsightly forms, it may have trivial and vulgar subjects, its greatest excellence may be in portraits—in fact, it may deserve most of the abuse which befalls it, but the charm of nature is never wanting. Now this praise cannot be bestowed on any other modern school; and small as it is, yet it is a genuine morsel, to be found in all the great Italian works from Raffaello down to Claude (who may be considered an Italian) in all of which you find the charm of nature. This is the real basement of good design in painting; and although but a basement, yet it is one whereon we can raise, if we please, any kind of structure in art; we can safely use the antique—we can even deal in the grand forms of Michael Angelo with impunity, but always with this guide. It was this enabled the great English sculptor, Flaxman, (the greatest and most universal artist of modern times) to find out the essentials of Greek art, which the French have ever missed. But in painting it was more difficult to be found. The Italians found it, and carried art to perfection, for in the imperfections they had the courage and taste to leave it; which imperfections the French, in trying to take away, removed also the key-stone of art—they left out the charm of nature. In modern painting, perhaps, no one has gone so securely towards high art as Reynolds, but he stopped short; and in carrying the thing further, others ceased to have this solid characteristic, and we have ceased to care about their works. Yet we care about Reynolds as much as ever, with all his faults. Why is this?—he has the charm of nature. On the contrary, Lawrence, with fine qualities and a feeling for nature, sunk under the influence of fashion; and we may trace to him the long throat, small head, and little feet, with much of the mawkishness of modern English art. Wilkie may be regarded as the most perfect painter of the English school. He not only had nature, though not in all her charms, but he applied all the fine principles of art; he concentrated them, and produced a style new, as it was a combination of several *never before combined*; he took Raffaello's power of expressing the subject, his elegance of composition and even design, with Rembrandt's force and Tenier's mechanism, all bound together by the charm of nature.

This has to be done in English historical painting. The same principles must be extended and raised as we see them in the Italian schools. So far we are moral cowards in art, that in avoiding the errors of the French we are content to be like little children, fed with spoon meat. In our painting we are in leading strings, whilst we are full grown men in other things. This must arise principally from our strong feeling for nature when we attempt painting; for we tremble at the brink of a classic influence, because we fancy it is not to be carried out with nature. The same with highly imaginative works—we fall short by becoming tame and mawkish; so that portrait, landscape, and domestic scenes are the only things left to our wilful cowardice,

and these, as we do them well, we are determined shall be the only things we will do at all.

But now the historical field is opening to us in painting of the new Houses of Parliament, and we shall be forced into a bolder and more manly style of design. Let us not look at the French, or think that we are in danger of falling into their excesses, for we are *not*—it is *not in us*, if we wished for it; indeed, it is our *fear of it which keeps us back*. Let us, then, venture on the boldness of Italian art, that is, to do things without caring for the defects, but only thinking on the real and actual power *which lies in the sphere of painting, and of how little we have yet exercised it*. Our ancestors may not have been so handsome as the Greeks; but they were quite as manly, as full of genius, and have left us, *not works of art*, but enduring principles, institutions, laws, and a history of which we have now to *make works of art*. To this purpose Greek art would not be desirable, if we could have it. Englishmen transformed to Greeks would be as absurd as Greeks transformed to Englishmen. The Germans have succeeded in creating a style of design that is independent of the antique, though not nearer nature than the Italian, or with so much beauty. We, with our strong feeling for nature, may go still further, for we may use the antique as the Italians did, to make it our own; but it must be to gain something like power in design—something which shall shun the Gallic-Greek on the one hand, and, on the other, the influences of English fashion, both equally prejudicial to art. Surely here, as everywhere else, there are fine individual specimens of nature, if the artist will but take time to seek for them, for the English are considered to be a fine-looking people. In the great church processions of Rome, where there are many of all nations joined with the Italians, I always thought the Irish monks the most historic looking men. Yet, judging from modern exhibitions, one would think the English but an ordinary race, from the sovereign down to the artizans and beggars. Our women are considered to be the most beautiful in the world, whatever we may *paint and think them*; for in modern English art they are shown in every degree of languishment and lassitude, from the “Betrothed” to the “Forsakens,”—all of which, I should say, were the productions of the most immoral people in the world, even more so than the French, who only disgust, did I not know they were meant to represent high-minded English women, virtuous as they are accomplished. All this arises from defective design, for as it cannot produce style, it produces fashion; and so a hideous monster, in the shape of taste, becomes the order of the day:—hence these ambiguous ladies, and gentlemen as their companions, with pocket-book faces. A very little honest drawing will remedy all this, but it must be drawing alone on a cartoon, for colour and effect will paralyze it. Let us have a touch of bold art once more, even as good as Reynolds, and we shall see fashion bow to it as it did to him.

ON THE FORCE OF THE WIND AND SEA.

Observed at the Delaware Breakwater in 1830 and 1831, with some suggestions concerning the transverse sections of Breakwaters. By ELLWOOD MORRIS, Civil Engineer.

(From the American Franklin Journal.)

THAT the force of the sea and wind often operates with tremendous energy against objects which resist their action, is a fact well known; to measure this force with precision is from the nature of things impossible, and hence it is only by a close attention to the observed effect produced by the waves of storms, upon opposing objects, that the engineer is enabled to form a proper idea of the energies of an agitated sea, when roused by gales to the assault of works raised for the protection of harbours.

To form a well sheltered harbour upon a site fairly exposed to the ocean, is one of the most difficult problems which can be proposed for solution by the engineer, for such is the difficulty of forming a stable barrier against the sea, that notwithstanding all that has been done in erecting sea-works under the direction of the ablest minds, we can at this day scarcely, if at all, point to an artificial harbour in a dangerous roadstead, which has realized the expectations of its projectors.

To appreciate, properly, the active forces which we are to counter-vail, is the first step in framing plans for sea-works; and to add another to the number of observed facts bearing upon this subject, is the object of the present article.

In the years 1830 and 1831, the writer (then assistant engineer at the Delaware Breakwater) had occasion to notice particularly, the severity of the action of storms upon such portions of that work as

were then elevated above low water mark; the results of these observations we will now detail, merely premising first such brief account of the work itself as seems necessary to a full understanding of the subject.

The Delaware Breakwater was located and begun in 1829; it will, when finished,* consist of two detached dikes of rock, *the Breakwater proper*, a work of 1200 yards in extent, running in a line tangent to the seaward extremity of Cape Henlopen, and commencing at 500 yards distant therefrom; the *ice-breaker*, a work 500 yards long, lying obliquely across the prolongation of the line of the Breakwater, and distant from its western end 350 yards, at the nearest point; the Breakwater lies nearly in the original course of the ebb tide, trending E. S. E. and W. N. W., and will cover the harbour from the northern and eastern winds; whilst the ice-breaker (mainly designed to shelter the anchorage from ice drifting on the ebb,) bears E. by N. and W. by S., and will, at the same time, protect the interior from the winds of the north-west quarter; the contained angle between the horizontal projections of the two works being thirteen of the southern points of the compass, or $146\frac{1}{2}^\circ$.

This artificial harbour is located in Cape Henlopen road, just within the pitch of the Cape, and its site is fully exposed to the sea winds which blow directly in from the Atlantic ocean, over the whole arc comprised between E. S. E. and N. E. by N. around by the East, measuring seven compass points, or $78\frac{1}{2}^\circ$; whilst on the other hand, it is also exposed to winds sweeping an extent, for the most part, of deep water, upon lines of twenty miles long in the Delaware Bay, and including, in their field of action, the whole arc contained between the N. E. by N. and W. S. W., around by the West, being thirteen points, or $146\frac{1}{2}^\circ$; from the W. S. W. around by the South to E. S. E., an arc of twelve points, or 135° ; the roadstead is completely landlocked by the shoals of Broadkill, and the main strand in front of the town of Lewes, Sussex county, Delaware.

From the above statement it is evident that the roadstead under Cape Henlopen is wholly exposed to the winds of the north-east quarter, the severest that blow upon the American coast, and which fling upon the strand within the Cape those tremendous billows which are raised by the sweep of the north-east gales over a free range of ocean; whoever has witnessed the fury of these storms upon our sea-coast, will, from these remarks, appreciate the violence of the seas which sweep that perilous road, wherein the writer has himself seen fourteen sail of vessels stranded at the same time, and with the loss of several valuable lives.

The average rise and fall of the tide in Cape Henlopen road is five feet, the highest spring tides, in moderate weather, seven feet, whilst the highest storm tides have been known to attain an altitude of ten feet and more above the plane of low water.

In the case of breakwaters, rising abruptly as they do from the bottom of the sea, it seems probable that the augmentation of altitude which waves receive in running upon an inclined coast, is not produced by them, or if at all, in but a slight degree.

The stones forming the summits of breakwaters, when assailed by the waves of the sea, are solicited by two forces, one acting vertically upward, with the force due to the hydrostatic pressure of a column of water, equal in altitude to the maximum wave which assails the work, and which force we can estimate; the other is the horizontal force due to the progressive motion of the billows, the extent of which we have no means of determining.

We may make a practical application of these views as follows; the heaviest stone used in the construction of the Delaware Breakwater, consisting of trap rock, from the Palisades on the Hudson river, weighed 184 lb. to the cubic foot; whilst the lightest, being the Hornblende rock, from Quarryville, in the northern part of the State of Delaware, weighed but 165 lb. to the cubic foot;† the average weight of the materials being 175 lb. per cubic foot, or $2\frac{1}{2}$ times heavier than sea water.

* If it be completed upon the plan projected by Com. Rodgers, Gen. Bernard, and W. Strickland, Esq., Commissioners, and approved by President J. Q. Adams, on the 27th of February, 1829.

† The Hornblende rock referred to, as weighing 165 lb. to the cubic foot, was the Greenstone from Jaque's quarry. A specimen of Gray Gneiss, from one of Leiper and Crosby's quarries, was found at the same time to weigh 168 lb. to the cubic foot; and some Black Gneiss from Hill's quarry, on Crum Creek, weighed 177 lb. per cubic foot. All the specimens of the above rocks, of which the specific gravity was tried by the writer, were broken off from masses of stone delivered at the Delaware Breakwater, in the construction of which all these varieties were then used. The specific gravities of some specimens of similar rocks, from the same quarries, were subsequently found, by a committee of the Franklin Institute, to be somewhat greater than is above stated.

Fig. 1.

Let us assume, according to Arnott, the maximum altitude of waves to be twenty feet, then if we take the case of the Delaware Breakwater, where the storm tides rise ten feet, let *a*, in the annexed sketch, Fig. 1, be the top level of the storm tide, *b*, the plane of low water, *c*, the dry rubble foundation of the work thrown promiscuously from vessels into the water, *d*, a mass of stone lying upon the rubble foundation, with its base coincident with the plane of low water, and *e*, a wave of 20 ft. high, advancing from sea at high water in the direction of the arrow, the crest rising 10 ft. above the high water plane, and the trough falling 10 ft. below it; then it is manifest that though whilst the wave is upheaving near the margin of the work, it may not act very powerfully upon substances in front of its base, yet the moment it begins to subside, if it happens to be in the position indicated in the sketch, with its fore foot inserted under the mass of stone, *d*, it will exert upon that mass the upward hydrostatic pressure due to a head of 20 ft., and in an instant after the horizontal force due to the progressive motion of the wave; and thus, as it were, by successive pulsations, the waves possess the power of advancing forward immense masses of rock.

Now the upward hydrostatic pressure of a column of sea water 20 ft. high, would equal the gravity of a mass of stone weighing 175 lb. to the foot, if the vertical thickness of the latter were $= \frac{20}{2\frac{1}{2}}$, or near $7\frac{1}{2}$ ft.;* consequently, if the depth or thickness of the mass of stone were less than $7\frac{1}{2}$ ft., it would be advanced a little to leeward by each successive wave; but if it were of greater vertical thickness it would stand fast, and resist the hydrostatic and progressive action of waves, not surpassing 20 ft. in height.

Breakwaters are, however, occasionally subject to augmented violence, from the assault of waves during storms, owing to the partial removal of atmospheric pressure; a fact which has recently been observed by James Walker, Esq., F.R.S. &c., President of the British Institution of Civil Engineers, and which was mentioned by him at a recent meeting of that Institute, (as reported in the Civil Engineer and Architects' Journal for September 1841,) in the following words:—"At the Plymouth Breakwater, during the great storm in the month of February 1838, several of the largest granite blocks, weighing from three to eight tons each, composing the surface or pavement of

* Corroborative of this calculation, we find it stated in Lyell's Principles of Geology, that "on the Isle of Stennes, in the winter of 1802, a tabular mass of stone, 8½ feet by 7 feet, by 5½ feet in depth, was dislodged from its bed (by the sea), and removed to a distance of from 80 to 90 feet."

This quotation shows clearly enough that a depth of more than 5½ feet of stone is necessary to withstand the action of waves.

A similar circumstance is stated in the public prints to have occurred in a severe storm recently, upon the coast of Massachusetts, near the Boon Island Lighthouse, where "a huge rock 23 feet long, 16 feet wide, and 6 feet thick," which weighed probably 170 tons, was moved by the waves a considerable distance up an inclined surface; evincing there that a vertical depth of six feet of solid stone did not possess sufficient stability to resist the force of the sea.

How much more accurately than the moderns, the ancients appreciated the powerful action of waves against sea works, may be inferred by the following paragraph, quoted from Josephus, by Godwin, in the Trans. Instit. Brit. Archts., 1835-6.

"In order to form a port between Dora and Joppa, Herod, in the fifteenth year of his reign, ordered mighty stones to be cast into the sea at 20 fathoms water, to prepare a foundation; the greater number of them 50 feet in length, 9 feet deep, and 10 feet wide, and some were even larger than these."

Stone of these prodigious dimensions would be very likely to maintain their places in ordinary storms; and their magnitude is in striking contrast to the comparatively small materials used in modern breakwaters, which, as a necessary consequence, require incessant repairs.

the breakwater, which, although squared and dovetailed into the structure, and embedded in excellent cement to the extent of their whole depth, and thus forming a solid mass, were torn from their positions, and projected over the breakwater into the Sound.

"Mr. Walker attributed this to the hydrostatic pressure exerted beneath the stones, at the moment when the atmospheric pressure above had been disturbed by the masses of water suddenly and rapidly thrown upon the surface of the breakwater; blocks of stone were thus often carried to a great distance, not so much by the waves lifting them as by the vacuum created above by the motion of the water, which exerted at the same time its full pressure from below."

And as additional evidence that the formation of a partial vacuum is sometimes a consequence of the envelopment of sea works by high waves, Mr. Walker further stated, "that during a storm in the year 1840, the sea door of the Eddystone Light-house was forced outwards, and its strong iron bolts and hinges broken by the atmospheric pressure from within. In this instance he conceived that the sweep of the vast body of water in motion round the light-house had created a partial and momentary, though effectual vacuum, and thus enabled the atmospheric pressure within the building to act upon the only yielding part of the structure."

As both the above remarkable instances came professionally under the notice of Mr. Walker, we are bound to place the utmost reliance upon the inferences derivable from his statements; and they indicate conclusively that no lateral connexion by dovetails, or otherwise, will compensate for a want of depth of solid stone; but that we must rely for stability in the coping of sea works, chiefly upon the weight of a large mass of materials, so connected as to gravitate as one body; we must oppose pressure by weight, and counteract by gravity the action of forces resulting from a disturbed equilibrium.

The pressure of the atmosphere is about the same per superficial foot as would be produced by the gravity of $11\frac{1}{2}$ ft. depth of stone, weighing 175 lb. per cubic foot; therefore, if breakwaters were liable to be assailed by waves but 20 ft. high,* at the same time that the atmospheric pressure was wholly removed, their summits would require coping with a depth of stone wrought into a solid mass, equal to $11\frac{1}{2} + 7\frac{1}{2}$, or 19 ft. measured vertically.

In the nature of things, however, we cannot suppose that the whole pressure of the atmosphere would ever be removed from any point of the summit of a breakwater whilst a wave of the maximum height was acting beneath; and though this is very much a matter of conjecture, we may probably infer that under no circumstances would more than two-thirds of the atmospheric pressure be removed from any point; this would be counteracted by a depth of eight feet of stone, weighing 175 lb. to the cubic foot, and as we have shown that a depth of near seven and a half feet is necessary to withstand the hydrostatic pressure of a twenty-foot wave, we may finally infer that the summits of breakwaters should never consist of less than 15 ft. average depth of stone firmly bound into a solid mass, by clamps, dovetails, and cement, so as to gravitate as one body.†

* The maximum height attained by the waves of the most violent storms, at the sites of breakwaters, is such an important element in forming the plan of the work, that it ought always to be ascertained experimentally, (which would not be difficult,) by attaching a machine upon the principle of a self-registering tide gauge, to a pile well driven at the site, and properly braced against the sea.

† This principle of constructing sea works was adopted in Rudyard's light-house, built upon the Eddystone, in 1709, and which, after successfully withstanding the storms of half a century, was destroyed by fire in 1759; regarding it, Smeaton states that Rudyard "judiciously laid hold of the great principle of engineering," that "weight is the most naturally and effectually resisted by weight," and accordingly formed his light-house, near its foundation, solid, and mainly of stone, for such a height as he conceived would enable the gravity of the mass to resist the upward hydrostatic pressure of the waves, in case the water insinuated itself beneath the building.

This idea was not lost upon the able and sagacious Smeaton, who, in erecting the famous stone light-house which succeeded Rudyard's, built the first 30 ft. high from the foundation, solid, and so proportioned the walls and lantern above the fundamental solid that if their mass were reduced to a cylindrical shape it would add another solid column of about 20 ft. in height; so that in opposing the action of the sea, the Eddystone Light-house is equivalent to a solid column of stone 50 ft. in altitude.

Now from the above reasoning, $50 \times 2\frac{1}{2}$, or 125 ft., is the altitude of the wave, whose upward hydrostatic action this building is, by its gravity alone, competent to resist; and as the atmospheric pressure is never removed from the summit, whilst the utmost altitude of the jet of water which is sometimes thrown over the lantern is short of 100 ft., its superabundant stability must be manifest.

The courses of this celebrated construction being dovetailed and joggled together, so as to prevent movement laterally; as long as its materials are proof against decay, the immutable laws of gravitation will retain it in

The fact that continual repairs are rendered necessary, by the blowing up and sweeping away of portions of the pavements of existing breakwaters, during violent storms, strongly sustains the views taken in this paper, and shows but too clearly, that the mass of stone usually combined upon their summits, is deficient in the requisite stability.

The form in which the stone ought to be laid and connected together should (the writer believes,) be that of a semi-cylinder, the axis lengthwise of the work, and the base laid upon such an inclination seaward as may counteract sliding, and prevent the possibility of its overturning upon the harbour angle, for we know that on a level plane, one half the amount of force will overturn a body which is necessary to lift it.

In the case, then, of a breakwater similarly situated to that of the Delaware, stone weighing 175 lb. to the cubic foot, and exposed to the assault of waves not exceeding 20 ft. high, it would seem that the section shown in the following Figure 2 would be a proper one.

Fig. 2.

a, the high water line of spring tides, above which storm tides rise three feet or more; b, the plane of low water; c, semi-cylindrical mass of stone at least 32 ft. in diameter, thoroughly cemented and bonded together; d, fore shore securing the angle of the sea slope, to be mainly formed of cubical blocks of rough stone, weighing at least ten tons each; e, the general foundation raised to the low water plane by rubble stone thrown promiscuously into the water from the decks of vessels; f, cemented foundation prepared for the semi-cylinder, and having a top slope seaward of about six feet base to one foot rise.

The advantage of a semi-cylindrical solid (which must average 15 ft. deep vertically,) is that if in the construction it is properly bonded on the diameter, with thorough courses of dressed stone, whilst the blocks which form the curved surface are cut like arch stone, no one stone could be by any means extracted from its place if properly doweled laterally, and the whole would resist motion by its gravity as one solid mass; the interior backing or hearting of the semi-cylinder would be composed of rubble stone well set in cement mortar, and grouted full in low courses, divided into sections for the purpose.

It is a general idea that the forces acting against a breakwater are augmented by a great rise and fall of the tide, but from the above reasoning it would appear that such a rise and fall as will allow a wave of the maximum height of 20 ft. to exert its greatest energy; or a difference of 10 ft. between the top water of storm tides and the low water plane, (as exists at the Delaware breakwater,) will enable such waves to act with as much power upon sea works as any other variation of tidal surface, and hence a greater rise and fall than 10 ft. will not increase, whilst a less one would certainly diminish, the effects of the assailing waves.

The section of the Delaware breakwater, as planned by the Commissioners appointed by the President of the United States, in 1829, under the act of Congress of May 24th, 1824, was trapezoidal in its general outline, the sea slope having a base of 105 1/2 ft. to a height of 39 ft., and being profiled after the curvilinear figure to which the waves of storms had reduced that of the breakwater at Cherbourg; the top was fixed at 22 ft.,† and the internal or harbour slope at one to one, or 39 ft. base, the entire base being 166 2/3 ft. to a height of 39 ft.; the base of the section which we have proposed as sufficient for a similar work, is 160 ft., and the transverse area would be nearly the same as that of the breakwater in the Bay of Delaware.

Philadelphia, Nov. 1st, 1841.

position, and enable it to defy, as it has for 82 years defied, the utmost force of the Atlantic storms; unless, indeed, it should be assaulted, by waves more than 135 ft. high, which is not within the range of probability.

* Experience at the Delaware breakwater proved that by this process alone a rough stone work could be brought up with precision to a plane of two feet under the high water of neap tides.

† With the design of increasing it to 30 ft., if subsequently found necessary.

MR. CHARLES WYE WILLIAMS AND HIS BOILER PROJECTS.

In extirpating the heresies of hollow and obtrusive pretension, in our review of this gentleman's projects in the February number, we are generally conceived to have rendered an important service to the cause of practical science. It required little penetration to foresee that the performance of this service would subject us to much abuse and misrepresentation. An advertising patentee can hardly be expected to be thankful for any exposition of the fallacy of his projects; nor can the demonstration of the inefficacy of these schemes be supposed to be peculiarly acceptable to those compliant analysts who have ventured to speak most highly in their favour. We were willing, however, to encounter the opposition and obloquy of this party, from our sense of the necessity of resisting the growing practice of disguising empiricism in the garb of science. With this conviction we shall proceed to make a few observations upon the several rejoinders we have received to our former remarks;—not that we feel any sort of anxiety as to their effect upon our own reputation, or the conclusiveness of our former arguments, but that the articulate defence of the projects we condemned affords the fairest opportunity of exposing still more clearly their inefficacy and extravagance.

There is one point to which, at the outset, we think it right to advert, as it materially influences the complexion of the case. It is this: not only are the various arguments adduced in support of these projects intrinsically without any weight or moment, but they are actually inconsistent with one another. Thus Mr. Williams calls upon us to believe in the excellency of his boiler spikes, because their efficacy is "neither more nor less than the practical application of the well-known theory of conduction," whilst his more acute disciple A. S. calls upon us to put faith in the virtue of the spikes, upon the strength of something which he says is "sufficient to destroy all confidence in reasonings founded upon the ordinary hypothesis." So that, while one of these preceptors requires us to believe in the spikes because the received theory is certainly right, the other requires us to believe in them because the received theory is probably fallacious.

In our former article, when speaking of the spikes, we observed that they would speedily attain the temperature of that part of the flue where they were introduced. Mr. Williams has entered into a long and ponderous dissertation, for the purpose of showing that this is not strictly correct; a thing manifest enough if we be understood to have said that the small portion of the spike in the planes of the iron of the flue, or the portion thereto adjoining, is as hot as any part of the body of the spike upon which the hot air impinges: but this we neither meant nor said. Our statement may want precision, for it was not meant to be precise, but in the gross, and as applied to spikes of considerable length, it is substantially true; and this gentleman's objection to it is about as weighty as an objection to the statement of the distance between two continents in miles, instead of in feet, inches, and decimals of an inch.

The *modus operandi* of the spikes is thus explained by A. S.:—"We naturally expect that the lower extremities of the pins will attain a higher temperature than the exterior surface of the boiler, and we may conceive that that section of the pins which lies in the plane of the outer surface of the boiler may differ more or less in temperature from that of the outer surface itself; but the rapidity of the transmission of heat may proceed according to very different laws, and the greater difference of temperature between the extremities of the pins, combined with the greater facility afforded by increase of surface for the reception and giving out of heat, may occasion such an increased intensity of transmissive action as to cause a greatly increased flow of heat into the boiler." Mr. Williams, on the contrary, says "So far from these spikes attaining such high temperature, practice proves that so long as water is the recipient of the heat they convey, their temperature is in fact so low as to be touched without inconvenience, the heat passing through them as fast as it is received." Thus, whilst A. S. endeavours to persuade us that the spikes may be conceived to operate beneficially, by virtue of an increased transmissive action arising from the high temperature of their lower extremities, Mr. Williams assures us that the temperature of the spikes is not at all high—that they may be even touched without inconvenience—and that the heat passes through them as fast as it is received, so that no part of the spikes can ever be either hotter or colder than the water in the boiler. Yet these are the gentlemen to whom we are asked to pin our faith. With much of the dogmatism of infallibility, they are consistent in nothing but in being inconsistent.

In our former remarks we quoted a portion of a paper which appeared in the *Mechanics' Magazine*, and which purported to be a

report of a lecture delivered by Mr. Williams, in which, speaking of he spikes, he said "The half-inch circular portion of the flue plates which such pin has displaced is thus made to possess the faculty of transmitting as much heat as is received and absorbed by nine half inches superficial;" by which we understood, we said, that the pin had the effect of transmitting to the water nine times as much heat as the half-inch disc it displaced. "This," Mr. Williams now tells us, "is a mere gratuitous understanding of a very plain position. I did not give any *measure* or *quantity* of heat so transmitted; I merely said at much heat as is received and absorbed." Did not give any measure or quantity! What, then, is intended by a reference to inches superficial but a reference to measure or quantity? But we will not higgie about trifles: we are willing to accept any amended meaning that Mr. Williams thinks fit to give us; and he now wishes, it would appear, to be understood as having only said that as much heat is transmitted as is received and absorbed. Be it so. The improved proposition, if it mean anything, only means that as much heat is transmitted as is transmitted;—a truism we should have been sorry to lay at Mr. Williams' door, except for his own requisition to that effect.

We stated, too, in our former remarks, that if spikes were capable, by virtue of their superior quantity of surface, of augmenting the evaporative rate of a boiler, a small flue surface spiked would be equal in evaporative efficacy to a larger flue surface unspiked; and a certain ratio would subsist between the power of the spikes in accomplishing evaporation, and that of the ordinary flue surface. We did not care, we said, whether this ratio were 9 to 1, as stated by Mr. Williams, or 1000 to 999; but that, if the spikes were of any use at all, in consequence of their extended surface, a certain number of spikes would be equivalent in evaporative efficacy to a certain area of flue surface, or a certain ratio would subsist between the efficacy of flue surface and spike surface. If this were so, we observed, by making the quantity of spike surface greater and greater, the quantity of flue surface might be made less and less, the evaporative rate of the boiler remaining the same; so that by increasing the quantity of spike surface sufficiently, the flue surface might be eliminated altogether, and we might actually have a boiler generating steam without any flue surface at all. We also observed, that if a spike three inches long were capable of transmitting more heat to the water than a spike of one-eighth of an inch long maintained at the same temperature, the received theory of conduction could not be right, because in that case rapidity of conduction could not vary as the temperatures simply, but as the temperatures and masses conjointly; so that it would be not the degree of temperature which would determine the rate of conduction, but the quantity of heat. According to this doctrine it was plain, we observed, that a very large body, though cold, would communicate as much heat as a very small body, though hot, provided the absolute quantities of heat resident in them were the same; so that a sufficient extent of spikes, though cold, might boil water and generate steam, without the aid of a fire.

To all this what does Mr. Williams answer? That the auditory of some Polytechnic Society could not see the absurdity imputed to his projects; that he does not measure the quantity of heat transmitted by the mere surface of the spikes; that spikes, though they are beneficially available up to a certain length, yet that length is not infinite, but the length of three inches is practically the best; that the number, too, of the spikes must not be increased beyond a certain limit, else the hot air will not obtain access to their surfaces; and that how the extravagancies imputed to his projects are deducible from the well-known theory of conduction it does not become him to say. Now did ever any one hear such a reply to such an argument? We show this gentleman that his doctrines lead to absurd conclusions, and he answers us by saying that how such absurdity is chargeable upon the received theory of conduction is incomprehensible to him. It is not with the received theory we find fault, but with *his* theory; nor do we find fault with its absurdity alone, but also with the arrogance with which it is advanced, and the equivocal character of the expedients by which it has been attempted to uphold it. The received theory of conduction is reasonable enough; the *reductio ad absurdum* has no power over it: but this gentleman's theory, turn it as you will, is irreducible to anything except superlative nonsense, and yet it is ushered forth with as much parade and ostentation as if it were the greatest discovery that had been made for ages. But the Polytechnic Society cannot see its absurdity. What have we to do with that? Is it because others happen to be blind that we are, therefore, to put our eyes out? We know that there are persons in the world who have no very clear conception of where it is the sublime terminates and the ridiculous begins; and it would be an anomaly in the history of delusion, if a consummately preposterous project were not to have some admirers. But as such persons are usually too incandescently wrong-headed to attend to the dictates of sober reason, their conversion is as hopeless

as their authority is invalid; and it would be in every sense superfluous to address ourselves to them. With such we have no concern: nor is the Polytechnic Society anything more to us than Hecuba was to the Prince of Denmark.

But further; the mere surface area of the spike is not the measure of transmissive power. What then is the measure? or is there a measure at all? If amid all the riot and pretension we have witnessed, it should turn out that there is no measure of the beneficial effect of the spikes at all, is it possible to resist the conviction that the whole affair is a pitiful juggle, the effect of which is to delude the ignorant and unwary? And if there be a measure, why are we not told what it is? Again, it is said the transmissive power of the spikes increases with the length, but does not proceed beyond a certain limit, and three inches is the best length. But all this is unsupported assertion merely: the question is, *why*, as far as theory is concerned, there should be a limit to the beneficial length of the spikes. The spikes, we are told, operate in promoting evaporation by virtue of their surface—their heat-receiving and absorbing surface, as it is called. A spike three inches long is alleged to be better than a spike two inches long, because it has more surface; should not, then, a six-inch spike be better than a three-inch spike, for the same reason? It is no answer to tell us that such is not the case. The question is, *why* is it not the case? Why, if spike surface be beneficial at all, should twenty square inches not be better than ten?

Turn we now to what our correspondent A. S. advances in favour of the spike system. He begins by admitting the truth of the observation we made in our former article upon these projects, namely, that the spike theory is incompatible with the received theory of conduction, and that, therefore, one of the two must be wrong; but he adds that it is the received theory and all the world that is wrong, and the spike theory and Mr. Williams that are right. His line of argument is as follows:—

The experiments of M. Delarive, says he, show that the conducting power of some fibrous substances varies exceedingly, according as conduction takes place in a direction transverse or parallel to their fibres. Wrought iron, being a fibrous substance, may fall under the same law, so that heat may be able to penetrate much better in the direction of the fibres, as in the longitudinal direction of a rod, than across the laminae or fibres, as through the thickness of a boiler plate. He further says that it has been found that increasing the dimensions of a conducting substance in the direction of the conduction produces only a slight retardation in the passage of the heat; a fact, he says, sufficient to destroy all confidence in reasonings founded upon the ordinary hypothesis: that, therefore, the power of transmitting heat may depend on something more than mere difference of temperature; and the spikes may, consequently, be beneficial.

All this, though extremely hypothetical, is very specious; yet it admits, we conceive, of a very satisfactory and obvious reply. If, as A. S. assumes, heat penetrates with unusual facility in the direction of the fibres of wrought iron, it might certainly be conceived to be desirable to insert in the plate iron of the flue discs sliced from the end of an iron bar, or for forming the flue of iron, the fibres of which lay in the direction in which the heat was required to penetrate. But to justify the use of the spikes, it is necessary to suppose not merely that heat is transmitted more rapidly in the direction of the fibres than transversely to them, but that heat is transmitted more rapidly through a spike three inches long in the direction of the fibres, than through a spike half an inch long in the direction of the fibres. If the doctrine advocated by A. S. be correct, we may conceive that if all the spikes of a boiler were cut off at the level of the surface of the plate, the discs of iron left in the plate might render the flue surface more pervious to the heat, on account of the greater conducting power of the iron in the direction of the fibres. But this increased permeability would be impaired or extinguished, if the heat had to travel through a distance of several inches of spike before it reached the plane of the flue surface; unless, as we have already stated, it be held that the heat travels quicker through a very thick than through a very thin piece of iron in the direction of the fibres, an idea too preposterous to be entertained for a moment. Instead, therefore, of the argument of A. S. proving the advantage of the spikes, it rather proves that if they be already inserted in any boiler they should be all cut off.

But further; A. S. asserts that no regard is to be had to the received theory of conduction, because an increment in the dimensions of a body in the direction of the conduction only slightly retards the propagation of heat; in other words, because the increment of dimension and the retardation of conduction do not vary in the same ratio. But what of that? The common doctrine of conduction does not specify any particular ratio in which this variation shall necessarily take place. It only says that heat is transmitted through a thin piece of iron more

rapidly than through a thick piece of iron, and that more heat is communicated by a square inch surface of hot iron than by a square inch surface of cold iron. In this sense it is rather to be accepted as a self-evident truth than as a questionable hypothesis; and the endeavour to overturn this doctrine is plainly quite as hopeless as the attempt would be to disprove the most obvious truth in the whole range of our experience. Besides, if conduction do not vary as the temperatures simply, it must vary as the temperatures and masses conjointly. The quantity of heat, or what is equivalent, the quantity of matter, in a body will then become an element of the rapidity with which heat is communicated; and the admission of this element immediately throws us upon the "imperial absurdities" to which we have already adverted.

But perhaps the most extraordinary proof of the hollowness of A. S.'s doctrine is the fact that he is himself, it would appear, unable to listen to the consolation it affords. No sooner is the new doctrine propounded than it is thrown overboard, as a thing of no worth or moment, and our credibility is solicited in favour of another doctrine, which, we are assured, is so much in accordance with the laws of nature, that it ought rather to be adduced as an explanation than adopted as a hypothesis. This doctrine is only a reproduction of that analysed in our former remarks, as proceeding on the assumption that there is a stratum of cool air in the flues resting upon a stratum of hot air—a supposition which we showed was just as much in accordance with the laws of nature as that a stratum of water should swim on a stratum of oil. The hot air, impelled upwards by its buoyancy, will always rise to the upper part of the flue, and as soon as it is no longer hot from the transfer of its heat to the water of the boiler, it will descend by the sides of the flue to the level proper to its temperature, without any considerable intermingling of the particles of the ascending and descending currents, as supposed by A. S., and therefore without any considerable tendency from that cause towards an equalization of their respective temperatures. Nor can the rapidity of the current of the hot air through the flues interfere with the economy of these molecular movements; the current through the flues being merely a relative motion of the hot air and the boiler, and not of the particles of the hot air with respect to one another.

This explanation, then, of the rationality of the spike system entirely fails; but even if it did not fail it would be nothing to the purpose, for this doctrine of the mode of action of the spikes, whether good or bad, is not the doctrine of Mr. Williams. It is not the thing to which he has called upon us to yield our assent, and is, therefore, not the thing into which it has been our present purpose to inquire. We come back, then, to the very point from which we started. We have no alternative but to admit that the received theory of conduction as we have explained it is right, and it is equally inevitable that we believe the spike theory to be wrong, and this gentleman's whole project an ineffable absurdity.

We have hitherto confined our remarks to theoretical considerations only: were we to extend them to the practical bearings of the subject, the scheme would appear more preposterous still. And first it might be remarked, that all the spike theory *professes* to accomplish is to diminish, in some measure, the quantity of flue surface requisite to produce a certain evaporative effect. It does not profess to save fuel—to aid combustion—to increase the efficacy of the steam, or to diminish the expense of maintenance. Supposing even, therefore, the spike theory to be correct—supposing that a square foot of flue surface spiked were superior in evaporative efficacy to a square foot of flue surface unspiked, we do not believe that any practical man, whose opinion is entitled to respect, would recommend the adoption of the spiked surface. And the reason is obvious: the same benefit the spikes profess to confer is attainable by simpler and more trustworthy methods. Who is there among practical men prepared to maintain that a moderate extension of the flue surface, or the employment of an appliance to enable the feed water to extract the superfluous heat from the hot air proceeding to the chimney—expedients whose simplicity is obvious, and whose efficacy has been established by the experience of a century—is not more safe, and in every respect greatly preferable to this expensive, inconvenient, and untested innovation? A flue surface studded with spikes would not only be more difficult to make tight in the first instance, but would be almost impossible to keep tight in those situations where the heat was great. It is well known to practical men, that in the furnaces of marine and locomotive boilers even rows of rivets are objectionable, and are as much as possible avoided; and the head or nut of a bolt in the same situation is found to be very quickly worn away by the rapid oxidation its high temperature induces. If such be the fate of a piece of iron projecting only an inch from the surface of the plate composing the flue or furnace, what might be expected to become of a piece of iron in the same situation which projected three inches above the plate surface? How long

might a spike be expected to last, where even a bolt head is quickly burned away? We might proceed to show, that the spiking of flues would not merely render repairs more frequent, but also more difficult—that it would be inconvenient to clean, and in some measure dangerous to meddle with flues studded with these Caledonian stiletos, fresh from the armoury of Dircks and Co.—the unfortunate sweep or boiler-mender being reduced to much the same condition as Regulus in his barrel of nails, or as a heretic on the eve of being impaled upon the pious spike surfaces of the martyrology. We might also show that the salt which collects in the flues of marine boilers wherever there is a leak could only be detached from the spikes with great difficulty, some of the spikes, too, being probably broken in the attempt. But we feel that it would be a useless multiplication of words to enter upon such topics; we have drawn the veil sufficiently aside to show the fallacy and folly of this project, and we leave those parts of it which it would be superfluous to expose, to the judgment or compassion of our readers.

We had almost forgot to mention that the application of spikes to boilers is not a new idea. Spike boilers were in use many years ago in the United States—that hot-bed of preposterous subjects—and we are told that a spike boiler is described and figured in Gordon's book on locomotion. Such boilers of course did not answer. Mr. Beale of Greenwich attempted to rationalize the scheme ten years ago, by making the spikes hollow and filling them with water. But even with this modification, the project was found unproductive of benefit, and highly objectionable in many respects. After much labour and capital had been uselessly expended, it was in consequence abandoned.

Let us now proceed to render indelible our former remarks upon the illusory nature of the smoke-preventive project. The pretensions of this scheme to a superiority over all pre-existing schemes rest chiefly upon the allegation, that it is not smoke which is attempted to be consumed, but gas. We admitted, it will be remembered, the superiority of the smoke-preventive principle over that which has for its object the combustion of smoke, and we expressed our readiness to give this gentleman whatever credit might appear due to him, either for having been the first to propound that principle, or the first to practically apply it. But we denied that the principle of smoke-prevention was even attempted to be carried out in this gentleman's furnace—that his furnace could not therefore possess any superiority upon that score; and we showed that smoke-prevention had, previously to Mr. Williams' expositions, been advocated in an essay attributed to Mr. Bourne. These statements, if substantiated, will certainly reduce Mr. Williams' merits to a superficies differing from nonentity by a quantity incalculably small. Let us examine what is urged in opposition to them.

The difference between smoke and gas, it will be recollected, we stated was, that the one was the product of imperfect combustion, and the other was not the product of combustion at all, but of distillation merely; and we said that for this gentleman's furnace to be a smoke-preventive furnace it was indispensable that no combustion should be carried on in it—a condition we showed to be incompatible with any conceivable mode of working a furnace so constructed. We argued then that combustion must be carried on in this gentleman's furnace, if it were in action at all; and that it would be a mere delusion to pretend that because there were doors to the ash pit the fire could therefore be kept alive without a supply of air. To this Mr. Williams replies, that he is guilty of no such absurdity as that of excluding the air from the ash pit altogether; and that the doors he places upon his ash pit are merely for the purpose of regulating its admission. In other words, it would appear that the use of these mysterious doors is merely to regulate the draught—a purpose which a single damper in the chimney would accomplish. It would further appear to be admitted that air is allowed to enter the furnace, and that combustion is carried on therein; so that it is smoke, not gas, which this gentleman attempts to consume, and his furnace is, therefore, virtually admitted to be a mere smoke-burning furnace, as we proved it to be in our former analysis.

In our previous observations we remarked that one of the most serious objections to all smoke-burning plans was the necessity of admitting an excess of air into some part of the flue or furnace, the refrigeratory effect of which materially detracted from the calorific efficacy of the combustible parts of the smoke. Mr. Williams informs us, that in his plan an excess of air is unnecessary, *because* the air is thoroughly diffused; and he is kind enough to hint at the "chemical error" we are supposed to have committed in supposing an excess of air to be indispensable, inasmuch as an excess of air, he says, is rather a serious impediment than a necessary aid to combustion. We feel that an apology is due to our readers for entering upon the demonstration of truths with which every schoolboy is familiar; but we have no alternative between leaving this gentleman unconverted and de-

scending to expositions which every one of common capacity will esteem as trite, obvious, and insignificant.

The necessity for the admission of an excess of air, then, to accomplish the combustion of the inflammable matters existent in smoke, does not arise from an unequal diffusion of the air among the smoke, but from the co-existence of a large quantity of unflammable gas, the product of combustion, which is commingled with the matters sought to be burned. To descend to the phraseology of Mr. Williams, the unflammable gas operates unfavourably upon the combustion of the inflammable gas *mechanically* by the interposition of its atoms, and *chemically* by the absorption of heat. The latter of these evils might be obviated by raising the unflammable gas to a high temperature, but the former is insuperable so long as the quantity of oxygen is unvaried, and is greater in amount in proportion as the quantity of unflammable gas is large. To take an extreme case; suppose that in every cubic inch of smoke there were only an atom of combustible matter present—the rest being all incombustible gas arising from combustion—and suppose that to every cubic inch of smoke two atoms of oxygen were admitted; what chance would there be that these two atoms of oxygen would come into sufficient proximity to the combustible atom to fulfil the conditions indispensable to combination? It is idle to talk of diffusion as a remedy for this evil; the difficulty is not that the gases are insufficiently mixed—for we have supposed the mixture to be homogeneous—but that the atoms are too far apart, and that an incombustible substance is interposed, which separates the atoms to be combined as effectually as if there were a wall or partition between them. This difficulty is only to be mitigated either by increasing the proportion of the combining substances, so as to render the quantity of the incombustible gas relatively less, or by so increasing the quantity of the supporter of combustion as to afford some reasonable prospect that the combustible atoms, when equably diffused, will be sufficiently near *some* of the atoms of the supporter to be within the range of combining attraction. The latter expedient is the only one available in practice, and this expedient is in effect neither more nor less than the admission of an excess of air into the flue or furnace, the word "excess" meaning a greater quantity than is proper to atomic saturation. In all smoke-burning furnaces, then, it is necessary to admit an excess of air into some part of the flue or furnace, to accomplish the combustion of the inflammable parts of the smoke; and this excess of air, by its cooling agency, diminishes the available quantity of heat the combustible parts of the smoke would otherwise surrender. Any diffusion appliance, whatever be its merit, leaves this difficulty untouched; and this, the chief obstacle to the success of all smoke-burning projects, attaches as much to this gentleman's furnace as to any other.

But further; Mr. Williams observes "I am told the sole peculiarity of my plan is that the air enters by a greater number of holes than usual. Will the reviewer inform your readers whether this peculiarity be not the very one which characterizes the Argand burner? Again, whether of two smoke-burning projects the least objectionable is that which admits the air at one hole or at many holes, it would be irrelevant to inquire. Now, Sir, that is the real point worth inquiring into, and this blinking the main question at issue will not go down with your scientific readers." If our scientific readers do not do more than blink at this exposition, the fault certainly does not lie with Mr. Williams. We thought the question had been whether this gentleman's furnace were a smoke-burning or a smoke-preventing furnace; but it would appear that the claim to the title of a smoke-preventing furnace is relinquished, and the real point now to be determined is whether this smoke-burning furnace is better or worse than other smoke-burning furnaces. This is at least intelligible; yet in the face of this announcement, and in the very same paragraph, we are told that this furnace is no more a smoke-burning furnace than the Argand burner is a smoke-burning lamp. The Argand lamp and the Argand furnace, we are told, very closely resemble one other—and in what respect? there are small holes in both.

In our former remarks, we stated that it was smoke, not gas, that was generated in this gentleman's furnace; and that whether the air were admitted by one hole or by a thousand holes, the nature of the thing to which it was admitted could not be altered thereby. But because an Argand burner consists of a tube perforated with small holes, and is a smoke-preventing arrangement, this gentleman's diffusion apparatus, being also composed of tubes perforated with small holes, is said to be a smoke-preventive arrangement likewise. The substance to which air is supplied through one hole, though smoke, is no sooner supplied with air through many holes than it immediately is turned into gas; so that we have only to apply this very reasonable doctrine to prove that the infusion which, when made in an ordinary vessel, we are wont to distinguish by the term coffee, will inevitably be transformed into chocolate, or something still more wonderful, if

made in a coffee-pot distinguished by small holes of the patent diffusion description.

We are perfectly aware, in common with every one who has not been educated in Caffraria or Timbuctoo, that gas may be burned with smoke or without smoke; and we are willing to admit—if the admission will gratify this gentleman—that the Argand burners of Regent-street are much better calculated to promote perfect combustion than the barbarous expedients of the butchers' stalls. But the question is not which of these appliances is calculated to accomplish combustion most completely, but whether the æriform matter proceeding from the orifices of the Argand burner and from the pipe of the butcher's stall is the same or different: whether if the gas, as it emerges from the orifices of the respective tubes, were to be separately collected and analysed, it would be in the one case found to be genuine and veritable gas, and in the other smoke merely. That such would be found to be the case we do not believe. We do not believe that the circumstance of æriform matter, or any other matter, being made to flow through a large hole, or through a small hole, can change its specific and proper character—that the size of the orifice through which it escapes determines whether a substance is smoke or gas, or whether a furnace is a smoke-burning or a smoke-preventing one. To talk about Argand burners, as if any species of burner could convert a gasometer of smoke into a gasometer of gas, is idle and ridiculous; and to compare a furnace with an Argand burner because it is furnished with small holes, is just about as rational as to compare it with a patent coffee-pot, or a kitchen strainer—inventions which participate in the same distinctions.

But an excess of air, it is said, is unfavourable to combustion. We know it well. Too much air, if admitted into the flue or furnace of a boiler, will augment the generation of smoke as effectually as too little; but this is caused not by an excess of oxygen, but by a defect of temperature, and has no more relation to the question before us than the allegation that though a candle to burn properly must be surrounded by air, yet a blast of air will extinguish it. In practice so much cold air may be admitted into a furnace that its temperature will fall beneath the point necessary for the inflammation of the combustible gases evolved, and their combustion may thus be prevented, not by an excess of oxygen, but by a destitution of heat. But the quantity of cold air to which this effect is due is much greater in amount than the excess requisite for the combustion of the smoke; and the inflammation of the gases may be maintained either by diminishing the quantity of air admitted, or by elevating its temperature. The antiphlogistic property of the influent air, then, is not one of its specific and necessary characteristics, but one accidental to its temperature merely, and does not in the least invalidate the necessity of admitting air to smoke *in excess*, to achieve the combustion of its inflammable portion.

To correct the impracticability of apportioning the admission of air in an ordinary smoke-burning furnace to the perpetual fluctuations in the quantity of smoke evolved, Mr. Williams says "I separate the air into two supplies, thus rendering them more manageable, and what is more important, less liable to interfere with and mar each other's objects; a system, too, which has also this practical value—the causing them to be to a great extent mutual correctors of each other's defects." This intimation has certainly the merit of being hieroglyphical and cabalistic enough to defy criticism, and precludes any very specific rejoinder. We must, therefore, be content to remark, that as it is an intimate admixture between the atmospheric air and the gaseous matter, whatever be its nature, which proceeds from the fire, that this gentleman professes to accomplish, his arrangements, supposing them to perfectly attain that object, and that smoke-burning is assumed to be desirable, will be valuable or not, just in proportion as the same end is attainable or unattainable, by other or simpler means. Now, the admission of a sufficient quantity of air to the smoke, or the thorough diffusion of that air, has never been found to be a point of difficulty. Indeed there is no furnace whatever, in which, by a proper regulation of the draught and of the depth of coal upon the grate, any quantity of oxygen may not be enabled to ascend to the smoke through the fire. In scarcely any furnace does all the oxygen which enters the ash pit enter into combination with the fuel; a part almost always escapes in its uncombined state through the burning embers, and by the mere regulation of the draught and of the thickness of the incandescent stratum, this quantity of oxygen may be made as great or as small as may be desired. As this oxygen ascends not in one part of the grate, but through every part of it, it must be necessarily equably diffused among the incomcombustible gases and inflammable substances present, and must, moreover, be of as high a temperature as the fire in its passage is able to impart. If this adequate supply of oxygen equably diffused among the smoke be attainable in any ordinary furnace—and that it is must be perfectly self-evident—wherein lies the necessity or benefit of this gentleman's diffusion apparatus? Not only

can the requisite quantity of oxygen be let in to the smoke through the fire, and be equally well diffused without any apparatus at all, but the oxygen so let in will, moreover, be of a high temperature—a condition highly favourable to combustion. As to the air being admitted in two supplies or in a hundred supplies, that point is one of perfect unimportance. The only point of moment is whether the requisite supply of oxygen is present, and that oxygen is equably diffused; and if this condition be fulfilled, it matters not one iota how the oxygen got there, or by what means its diffusion has been accomplished—whether by the instrumentality of diffusion orifices, or whether it has made its way through the interstices of incandescent fuel upon the bars of the grate.

We spoke so fully in our former remarks of the inherent and necessary defects of smoke-burning arrangements generally, that it would be superfluous now to say anything more upon the subject. This gentleman's invitation to investigate the merits of different smoke-burning schemes, if accepted, would lead us into an invidious and unprofitable discussion. Of two plans positively injurious, there is little advantage to be conferred by showing that one is rather worse than the other. It is sufficient to show that both are worse than the methods most known and practised, and are, therefore, undeserving of further attention. Furnaces of the ordinary description will produce very little smoke, if the coals be spread thinly upon the bars, and the draught be pretty good; for in that case a sufficiency of oxygen will find its way through the fire to accomplish the combustion of the inflammable parts of the smoke. It is usual and beneficial to have a dead plate at the mouth of the furnace, and a few holes in the furnace doors, the purposes of which are obvious.

But it is time that we should turn to A. S., to ascertain what he is able to advance in favour of Mr. Williams' smoke-preventing pretensions. His whole argument rests upon the imputed fallacy of the definition of smoke given in our former article, and it is, therefore, sufficient for us to show, in reply, that the definition we there gave is the natural, universal, and correct one. We defined smoke to be "the product of imperfect combustion"—a definition A. S. altogether repudiates. "Smoke," says our correspondent, "is here defined to be the product of imperfect combustion; but what are we to understand by the term imperfect combustion? there is no such thing in nature. Who ever heard of imperfectly-formed carbonic acid or of steam without a saturating equivalent of oxygen?"

In saying that combustion, which is an act of chemical combination, is imperfect, we can only be supposed to mean that the process of combination, owing to the co-existence of some such agency, has not been perfected:—in other words, that although some of the atoms of the one body have entered into combination with some of the atoms of the other, yet that the remaining atoms have not entered into combinations, owing to their subjection to some such influences as those we have indicated. The use of the term imperfect combustion, then, does not involve the supposition that carbonic acid is imperfectly formed—although it is not certain that there may not be a species of combustion which generates carbonic oxide—but that the act of forming carbonic acid in quantity proper to ingredients present, has not been completed or perfected. Any other supposition would not only be gratuitous, but opposed to the whole tenor of chemical science, and it is difficult to suppose our correspondent to have believed that an opposite tenet was held by us.

But again, the term "imperfect combustion" is that employed by all chemical authorities, and what perhaps is more to the present purpose, it is that employed by Mr. Williams. We feel that it would weigh but little with our correspondent to adduce the authority of Sir H. Davy, Dr. Dalton, Berzelius, and Dr. Thomson, showing that smoke is the product of imperfect combustion caused either by the want of oxygen or the want of heat. But our correspondent cannot surely refuse to bow to the authority of Mr. Williams. Let him turn, then, to the 24th page of the appendix to Mr. Williams' treatise, and he will find an extract from the specification of his patent which runs thus:—"Smoke is the result of the IMPERFECT COMBUSTION of the volatile products." After this we feel it would be superfluous to say another word on the subject.

Our correspondent says that Mr. Williams' furnace has been very successful in practice, which is probably true enough, if we look upon success as the capability of being endured, or as a measure of beneficial effect, such as other smoke-burning schemes have succeeded in attaining. There is, perhaps, no smoke-burning scheme whatever of which the same thing may not be predicated as our correspondent alleges of this; for as we formerly mentioned, smoke-burning schemes may, with great care, be rendered instrumental in saving fuel, but in the aggregate of continued and ordinary working, there is always either a diminished efficiency or an increased consumption. In the evidence given before the committee of the House of Commons on

the smoke nuisance, in the year 1819, a multitude of schemes are mentioned as having been found to answer extremely well, and some are said to have been then in successful operation in the large London breweries. Yet these same schemes have all been discontinued—a result hardly compatible with the supposition that their continued use had been found advantageous. Upon what principle we can form any other anticipation relative to this smoke-burning project, than that it, too, will be discontinued, so soon as the stimulus of novelty has subsided, we are altogether at a loss to imagine. Besides, if our correspondent be prepared to assert that this scheme has been beneficial in some cases, and we at once admit, under the qualifications we have stated, that such may be the case, is he prepared to deny that, in other instances, it has been detrimental? Has it not been discontinued already in several factories in Liverpool and Manchester, and was not its employment in the case of Messrs. Hamnett & Co.'s furnace, productive of serious injury to the boiler, from the alternations of temperature consequent upon the alternate streams of flame and cold air flowing from the diffusion orifices and impinging upon the iron of the boiler? It would be unfair, we admit, to condemn any scheme, because it may have failed once, or even several times; for the failure of a good plan may be induced by imperfect machinery, carelessness, or even design. But neither can the reputation of a few successful applications win our entire confidence, especially when the plan is unaccompanied by any manifestation of qualities adequate to the production of the alleged advantages. It is so manifestly the interest of patentees to exaggerate the merits of their own projects; and even where emolument is not an object, an ephemeral reputation is sometimes so highly valued, and the tendency of human nature to regard its own productions with partiality is so powerful and universal, that all representations coming from an interested party are to be received with caution. If this be the rule with rational projects, shall we dispense with its observance in the case of projects whose rationality is more than problematical? Shall we, upon the questionable authority of a patentee, accept statements as indisputable which not only transcend the bounds of credibility, but are inconsistent with the dictates of common sense?

To the charge which might be thought to be involved in our account of the extraordinary circumstances under which this gentleman's ideas relative to the superiority of the smoke-preventive principle, appear to have been developed, no defence or explanation is even attempted to be offered. We are told, indeed, that if smoke prevention be good under the auspices of Mr. Bourne, it cannot be bad under those of Mr. Williams, a proposition sufficiently self-evident, but altogether foreign to the question. The point to be determined is not whether Mr. Bourne's plan is good or bad—an inquiry with which we have nothing to do; but whether Mr. Williams did or did not obtain the ideas of Mr. Bourne in confidence, and appropriate them to his own uses. Upon this point Mr. Williams is silent. He does not say that Mr. Bourne's essay was not published anterior to his book, that Mr. Bourne's patent is not of an earlier date than his patent, and that antecedently to the dates of books or patents, Mr. Bourne did not communicate to him, in confidence, his ideas, upon the expediency, practicability, and advantage of the smoke preventive system. It is true that this system is not carried out in Mr. Williams' scheme, the proposed object being defeated by the injudicious character of the arrangements, and that therefore this furnace has no title to the character of a smoke-preventing one. But the desire that it should be such is palpable enough, and the existence of this desire and the boasted possession of smoke-preventive properties, are quite as conclusive, so far as this question is concerned, as if that desire and those properties had been actually realized. Whatever credit, then, is claimed upon this score of smoke prevention, or whatever credit is claimed for the announcement of the superiority and practicability of that system, is not merely unclaimable by this gentleman, but it is questionable whether he can extricate himself from all suspicion of having appropriated as his own what he must have known to be the property of another. It is true that the thing taken, supposing that the fact of such appropriation were established, is of little or no value; for the fact of the abstraction from one person of a smoke-preventing project and its appropriation or attempted appropriation by another, can hardly be supposed to be productive of much benefit to the one, or of much detriment to the other. But the insignificance of the value cannot influence our sentiments respecting the quality of the act, unless it be to suggest that if an insignificant object be capable of inducing a deviation from strict propriety, a more important inducement may be expected to render such deviations more extensive and less reluctant. As regards this case, we refrain from making any specific charge further than to say that Mr. Williams has not even noticed the statements we formerly made upon this branch of the subject, that those statements must therefore be supposed to be correct, and we are pre-

pared to substantiate them by the fullest evidence, and that of the conclusions involved in those statements we must leave every reader to make his own estimate. We therefore dismiss the subject with the general remark, that the public is, we believe, perfectly capable of appreciating the merits of a projector who is indebted to his invention for his facts and to his memory for his inventions.

MR. VIGNOLES' LECTURES ON CIVIL ENGINEERING, AT THE LONDON UNIVERSITY COLLEGE.

SECOND COURSE.—LECTURE IV. LAYING OUT RAILWAYS.

In the preceding lectures the subject of the motive power had been much enlarged upon, from its necessarily influencing the manner of laying out a line. Mr. Vignoles said the student may be referred to study, at greater leisure and in detail, the principles laid down in the works of various authors on laying out both roads and railroads—M'Neill, Parnell, Navier, Tredgold, &c.—and the rules laid down by them may be taken as sound first principles, though modified at present by the improvement of motive power and other causes which could not have been known *a priori*. Railroads have so completely superseded many of the principal roads, and the public convenience has been thereby so much interfered with, that it becomes a matter of importance to run the trains as often as possible, and this becomes a new element in laying out a line of railway. Hitherto this has been done under the impression that the engines would always carry maximum loads, and though it is true that main lines radiating from the metropolis, into which a number of tributaries fall, may be laid out with a view to maximum loads, yet it becomes a consideration whether it would not be better in general to lay out railways with a view to the trains going often, and with light loads, and thereby to make the gradients suitable to the ground over which they pass. On this subject Mr. Tredgold has always judged soundly. Seventeen or eighteen years since he made various calculations on the comparative expense of ascending and descending inclined planes, and of cutting them down to a level; and he states, in his *Treatise on Railroads*, that it will be much less expensive to follow nearly the undulations of the surface, and "if a few examples (of the comparative expense) be added, it will assist in removing those extravagant notions of cutting and embankments, by which the capital of the country is wasted in unprofitable speculations." But the practice of engineers has been directly opposed to this, although we had almost a daily improvement in locomotive power, affording means of overcoming the difficulties of steep gradients. Before determining upon the inclinations which he will adopt, therefore, the engineer should make estimates of the comparative expense of forming and working flat gradients, and gradients of an inferior description, and it will be found that gradients of 50, 60, and even 80 feet in a mile, may be advantageously introduced, especially where the traffic is not very considerable. And if lines were laid out upon these principles, instead of the traveller being overcharged with the expense of the capital sunk, as at present, he would be charged with the expense of the motive power, which bears a very small proportion to the total amount exacted from passengers. Locomotive power only is scarcely more than 1d. per passenger per mile, whereas the ordinary charge to passengers is 2d.; and this may explain why railway companies do not lease the working of their lines, for they make most of their profit as carriers, and not as capitalists.

In laying out railways there are generally two distinctive descriptions of country which the engineer meets with, each of which requires a different description of treatment with respect to his operations. The first is where there is a certain summit or ridge of country to be surmounted; the rule in this case will apply both to roads and railroads—viz., to get a uniform inclination, if possible, up to the summit; but if that be not practicable, to lay out the line in stages, taking care that, having once attained any intermediate elevation, the line does not, if possible, descend again. In a country of this description there will be much more difficulty in the details than in striking out the first general idea, for it will require the greatest care and patience to lay out the line so as to ascend to the summit at the least possible expense, by winding along the sides of hills, and crossing lateral valleys and ravines to the greatest advantage, &c.

The other description of country is where the extreme points of the line to be laid are on a level, or nearly so, and the ground varies. In this case his judgment will be principally exercised in determining the general direction of the road, in taking trial levels to determine the line of least cutting and embankment, in avoiding valuable property, and in securing the largest amount of traffic; and in a country like England, which is so full of improvements, gentlemen's seats, roads, streams, &c., it is an exceedingly complicated duty to make choice of the best line under such circumstances; but it may be laid down as a general rule, that in any difficulty it is always better

to incur a positive known expense, which will not entail future liability, than by diminishing the expense in the first instance to run the risk of undergoing future loss. Thus, for example, if a line of railway upon a slight embankment should cross a road on the surface of a wet or marshy country, it will be better to raise the road to a sufficient elevation to pass it over the railway, though the height of the bridge and approaches be thereby greatly increased, than by slightly lowering and passing it under the railway at a greatly reduced expense, to render it liable to be continually laid under water. And these are the kind of circumstances that require so much care and consideration on the part of the engineer, to enable him to judge of the comparative amount of cost and maintenance of the different systems which he can adopt, and to regulate his designs accordingly. Now we might go on thus increasing railway gradients until they approached nearer and nearer to those of a turnpike road, were it not for the difficulty of regulating the descent of them with safety. On a turnpike-road, writers have suggested that from 1 in 36 to 1 in 40 is the best slope, because horses may gallop down without danger, and, at the same time, it is a good trotting road upwards. But on railways it is not safe to go down such inclinations as that. Professor Barlow lays down that when the inclination is greater than 1 in 160 all advantage from gravity in the descent is lost, from the necessity of applying the brake, and he has formed tables to show the amount of loss sustained in the ascent; thus, he states, that going up one mile of 1 in 100 is equivalent (of course with a maximum load) to going $2\frac{1}{2}$ miles upon a level; but he will not allow that any corresponding advantage is gained in the descent of this, or any plane steeper than about 1 in 180. Now, if this be the case, we must have a totally different set of elements in forming lines of railway from what I have been laying down. But, as has been already stated, this is not the case in practice, for trains can have, with perfect safety, the full benefit of gravity on all descents up to 1 in 100, and the engines seldom carry maximum loads. The same line of argument has been pursued with respect to turnpike-roads, where, however, there are many circumstances in operation which do not occur on railways—such as the unsteadiness of horses and coachmen, which influence the question; but the great point to be considered is whether it is most economical to lay out railways with respect to stationary or to locomotive power. On this subject M. Navier very sensibly remarks, that great rapidity being the characteristic of railways, it has been considered necessary to employ locomotive engines, which system presents an important advantage in being able to increase gradually the number of engines as the demands of commerce require it, whereas, on the stationary system, it is necessary to provide at once for the greatest amount of traffic that can ever occur. But in the event of this increase, we have still the means of using light and frequent trains for transporting a heavy traffic over a line of inferior gradients, and reducing the charge of the interest of that capital to the public. But whatever be the description of country which the engineer may meet with, he should first of all make or procure detailed plans on the largest scale, and upon them lay down a number of surface levels, and from them, as from a model, to find the line of least expense and greatest accommodation. The magnificent Ordnance Maps of Ireland, from their great scale and numerous surface levels, will render the task of the engineer in that respect easy, should the long-deferred introduction of railways into that country be ever carried.

LECTURE V.—ON THE COMPARATIVE ADVANTAGES OF DIFFERENT RAILWAYS.

THE class will, no doubt, be inclined to think that I have dwelt too long in the first four lectures of the present course, upon the principles of economy in motive power, but I assure you, that if, in after years, any of you follow up the profession, you will find the subject one of the most vital importance. I shall this evening draw your attention to the different elements of comparison which should guide the engineer in forming a selection from different proposed lines of railway, and shall take, as a text-book for that purpose, Mr. M'Neil's translation of M. Navier's work *On the Means of Comparing the Respective Advantages of Different Lines of Railway*—a work which I highly recommend for your private study, on account of the clearness and accuracy of the views it contains. M. Navier states "that the elements of comparison of different lines of railway may be divided into two heads; first, the establishment of a very rapid mode of transport—a consideration which should give a preference to the shortest lines, the velocity being supposed to be the same in all; second, the increase of wealth which may result from the establishment of a line of railway. The construction of a railway, like that of a common road or a canal, is favourable to the advancement of wealth; in the first place, because the actual expense of transport in this direction is diminished; and, in the second place, because this diminution in the cost of transport increases the value of the neighbouring properties, facilitates the establishment of new works, and increases production;" and the saving effected is not merely a private advantage to those individuals who may be directly benefitted by it, but is so much actual increase of the wealth of the country at large. "The first of these effects—that is to say, the diminution obtained on the actual cost of transport—is the cause of the second, so that

this diminution is the principal circumstance, and that which should be principally considered." Taking it as established, therefore, that diminution in the cost of transport is the principal thing, we come to the result that the cost of motive power, on which this is dependent, is the leading point to be attended to in the formation of any line of railway. Indeed, M. Navier goes so far as to say that this is almost the only circumstance to be attended to; in his own words, "we should even say that the rate of reduction which is obtained upon the actual cost of transport, by the establishment of a new communication, is almost the only circumstance which should be thought of;" but he goes on to say, very justly, "it is also necessary to consider the quantity of goods which is carried, or which may be carried hereafter, in this direction," for the very essence of the railway system is to increase its own traffic; "for it is evident that it may be less advantageous to the country to produce a great economy in the cost of transport upon a line where there is but little to carry, and more advantageous to produce a less economy upon a line where a large quantity of merchandise is carried." These are the principles which I have been endeavouring to impress upon your minds, and which, from their importance, I cannot too often repeat. "It is, therefore," says M. Navier, "generally necessary to take into consideration, in the comparison of different lines, the quantity of traffic which may be established on each, and even the increase in the value of properties, and the development of production to which the establishment of these lines may give rise respectively, according to the nature of the countries which they traverse." I would observe, as a passing remark, that the word *développement*, in French, generally refers to length; thus the development of a line of railway will be spoken of—meaning the length of that line—whilst, in English, the word refers to an extension of superficies. M. Navier does not go minutely into the examination of these last elements of the question, which rather belong to statistics and political economy than to engineering, but confines himself to the "consideration of the reduction which the establishment of a railway can effect upon the actual cost of transport—a most important consideration—to which, as already remarked, it is always necessary to attend; and this will form, in every case, the principal element of the comparison between different lines, and often leads to determinations purely geometrical or mechanical, and, consequently, exempt from arbitrary deductions."

M. Navier then goes on to state, that "the cost of transport on a railway, as upon a road or canal, depends on two principal points, which it is necessary to distinguish and consider separately; the first of these is the expense of constructing the railway, and the second is the expense of conveying the goods on the railway, when it is constructed. The expense of the construction of the railway is independent of the quantity of merchandise and of passengers that will pass over it. The expense of transport, properly speaking, upon the railway supposed to be constructed, depends, on the contrary, upon the quantity of merchandise or of passengers—that is to say, all other things being equal, the expense will evidently be in proportion to the tonnage." Now, a few years back, the whole time of the House of Commons was taken up with comparing the merits of rival lines of railway, for no sooner was one line proposed than directly a rival line was started. It is well known that, for the Brighton Railway, four different lines were proposed—the discussion on the respective merits of which extended over a considerable length of time. But it is a curious fact, that, in all these discussions, the principle which has been laid down this evening was never once alluded to. Now, in the practical working of railways, the diminution of expense of transport is generally quite independent of the quantity of goods carried, for, after a line is constructed, the charges are generally arranged with reference to rival lines, or to the competition which may exist with the railway; and the interest of the money laid out is scarcely thought of, however much it may have entered into the *a priori* calculations. The Paris and Versailles Railways may be mentioned; two lines were started, one on each side of the river—the Government did not like to treat either party harshly, and passed both bills, and both lines are actually executed; and, from the great competition between them, the charges for transport of goods and passengers will probably bear little or no relation to the interest of the capital expended. There is, however, another element which renders the calculation of a very complicated nature. The railways are different from common roads or canals, over which, after they have been once constructed, the public have been left to find their own way—considerations of public safety render it necessary to incur great expenses in terminal and local stations, &c.; and there are also secondary expenses, such as the annual cost of repairs, police, and management, of which it may be said that they depend partly on the interest of the cost of constructing, and partly on the amount of tonnage carried. Now, from experience a general idea can be formed of the expense of these items, but, before going into the details, I will return to M. Navier, who says—"We may, therefore, admit, without falling into any serious error, that the annual cost of transport on a railway is, in all cases, formed of two parts—the one proportional to the expenses of the construction of the way, and the other proportional to the amount of tonnage carried; and we should also observe, that the cost of transport of one ton of merchandise cannot be specified, unless the number of tons which shall be

carried annually from one extremity of the line to the other be known." Now, hitherto we have been unable to determine *a priori* what these amounts are—but we can tell with great accuracy what they have been on the different lines of railway now in operation. The following tables give the average of these expenses on several lines of railway:—

MERCHANDISE TRAFFIC.

Heads of charge.	Coal on colliery railways in the north.	Goods on the Liverpool and Manch. Rlwy.
Locomotive power—wages and repairs .. .	0.355*	0.425*
„ fuel .. .	0.025	0.125
Total .. .	0.380	0.550
Wagons .. .	0.190	0.227
Conducting traffic .. .	0.075	1.080
Maintaining railway .. .	0.208	0.307
General expenses .. .	0.100	0.354
Total cost .. .	0.953	2.518

* Per ton per mile—in decimals of a penny.

PASSENGER TRAFFIC.

Heads of charge.	Lond. & Manc. Railw.—average 60 passengers per train.	Dublin & Kings-town Railw.—av. 40 passengers per train.
Locomotive power—wages and repairs .. .	0.170*	0.173*
„ fuel .. .	0.100	0.115
Total .. .	0.270	0.288
Coaches .. .	0.054	0.031
Conducting coaching .. .	0.104	0.113
Maintaining railway .. .	0.085	0.050
General expenses .. .	0.091	0.174
Total cost .. .	0.604	0.656

* Per passenger per mile—in decimals of a penny.

Taking the Liverpool and Manchester Railway as an example, we find the number of passengers to average sixty per train. This may, on the whole, be considered as a fair average on all the railroads throughout the country. Seven years working of the same railway gives, as the average expense of locomotive power, 0.27d. or about $\frac{1}{4}$ d. per passenger per mile. The gradients do not exceed six or seven feet per mile, with the exception of the inclined plane, and this also is an average amount for most railways—in fact, fuel and wages are so nearly the same on all lines, that the expense of this head can be calculated with great exactness. The expense of locomotive power, also, is the only one which depends upon the gradients. The other expenses, which are independent of the gradients, are—coaching, conducting ditto, maintaining way, and general expenses, altogether amounting to 0.33d., which added to 0.27d. = 0.60d., or, in round numbers, three-fifths of a penny per passenger per mile for the expense of transport. Now, let us examine the relative expense of the merchandise traffic. We have, for the expense of locomotive power, 0.55d., or, in round numbers, $\frac{1}{2}$ d. per ton per mile; for the cost of wagons and secondary expenses, 1.97d., which, added to 0.55d., gives 2.52d., or, in round numbers, $2\frac{1}{2}$ d. per ton per mile as the actual cost of transport. Now, let us mark the very striking result of this comparison. Even with all the most recent improvements, and cutting down every expense that can be reduced, the mere transport of passengers costs three-fifths of a penny per passenger per mile, whilst that of goods is only $2\frac{1}{2}$ d. per ton for the same distance, and of this $1\frac{1}{2}$ d. may be thrown out, arising from other sources, leaving the cost of transport—passengers, three fifths of a penny per passenger per mile; goods, $1\frac{1}{2}$ d. per ton per mile. In the first case, we have an amount exceedingly high, in proportion to the present means of transport, whilst the second case presents a result as strikingly low. A ton of goods is equivalent to the weight of fourteen passengers, with 30 lbs. of luggage each.

When the loads to be carried are light, and the velocities at which they are carried considerable, the steepness of the gradients is a matter of comparatively little consequence, but as soon as the engine is loaded to its maximum power, the railway system becomes unable to compete with the canals, so far as relates to the carriage of goods. If these are the results offered to you by past experience, do you not see at once how it affects the question of

laying out lines in remote districts, where but a small amount of traffic can be calculated upon? Again, referring to the table, with reference to the difference between carrying slowly and carrying quickly, we find that the expense of locomotive power on the Liverpool and Manchester Railway is 0.55d., or nearly three-fifths of a penny, yet that the expense upon the best railways, where goods are carried at a moderate velocity, is only 0.38d. and the remaining expenses 0.57d., so that it comes to this, that we have—Liverpool and Manchester Railway, $2\frac{1}{2}$ d. per ton per mile; other railways, with moderate speeds, 1d. per ton per mile. M. Navier proposes a case not quite so strong, perhaps, as might be made out, and I will, therefore, refer to the Brighton Railroad for an example, the expense of which, for the 40 miles, has been about £2,600,000, or £60,000 per mile, the interest of which, at 6 per cent., is 10 $\frac{1}{2}$ per mile per day, which is the net receipt, after all expenses are paid, requisite to insure a decent interest to the shareholders. I shall not enter further into the question now, but if those students who are sufficiently advanced will take up the subject, they will soon be able to appreciate my arguments for increasing the limits within which gradients are usually kept—for, supposing the expense of carrying a passenger should be only $\frac{1}{4}$ d. per mile, yet, if you will calculate the additional expense of the interest of £60,000 per mile, you will find ruinous results.

M. Navier having said that the cost of transport is the chief point to be attended to in laying out a railway, goes on to determine the amount of power requisite to draw a given train over a given railway. The elder students will, in connection with this subject, be aware of the opinion which has been pretty generally entertained amongst engineers, that a rise of twenty feet per mile is equivalent to a mile in length. M. Navier says—"Let us observe that, upon a horizontal line, the power required to draw a given weight is considered as being equal to almost the two-hundredth part of this weight;" but, as I have shown in a previous lecture, the formula for the expression of this power will be $\frac{F}{n}$ taking F as the friction per ton, and n the number of pounds

in each ton, so that what M. Navier calls the two-hundredth part of the weight will be friction divided by the number of pounds in a ton. Taking the friction at 9 lb., we have $\frac{9}{200} = \frac{1}{22.2}$ nearly. At 11 lb., $\frac{11}{200} = \frac{1}{18.2}$; and I must here repeat what I have so often before stated to you, that, although experiments have been made, which give so low a friction as 4 lb. per ton, that, on an average, M. Navier is nearly right, when we take into consideration the numerous causes of friction. M. Navier considers the power required to draw a given weight "to be independent of the absolute velocity of transit, although there is reason to believe that the tractive power increases with the velocity." Now, it has been said that the friction is the same at all velocities. I cannot fully concur in this opinion. I think the axle-tree friction may be constant under all velocities, but that, from other causes, there appears to be, I will not call it an increase of friction, but an increase of resistance, the amount of which has not been satisfactorily determined. M. Navier goes on—"We conclude from this, that, in order to transport, with any velocity whatever, constant or variable, a weight, W , to a distance represented by a on a horizontal line, it is necessary to employ the power represented by $\frac{W}{200} \times a$ —that is to say, the power necessary to raise the weight, to the height $\frac{a}{200}$," or, in other words to transport a weight any given distance on a horizontal line, is equivalent to raising it the two-hundredth part of that distance in vertical height; and, although this is not quite correct, it is sufficiently so for general purposes. We have before assumed that it is the same thing to go a mile round as to go over a hill rising twenty feet in a mile. Now, a mile being 1760 yards, or 5280 feet, we have $\frac{W}{200} \times 5280$ as the power required, which is equal to raising the weight 26 ft. But as the friction varies, I think we have sufficient experience now to say it is about the same thing to rise 30 ft. in a mile as to go a mile round: but this is quite independent of the question, whether you should or should not allow on one hand, and deduct on the other, when the slope exceeds the angle of repose. I have explained to you, on previous occasions, the difference of opinion that exists on this point. Both Mr. Barlow and M. Navier allow the advantage up to a certain point, which they fix at about 1 in 180, beyond which point they consider the whole advantage gained to be destroyed by the necessity of putting on the brake. Now, in practice, we do not find this to be the case, until we come to 1 in 80, or thereabouts; however, we may take, as a general rule, M. Navier's concluding words on this subject:—"The length of the line remaining the same, the amount of power consumed to effect the transit depends entirely upon the length of the line, and the difference of the level of its extreme points." The practical result which I have endeavoured to lay before you this evening is, that the cost of transport is the cost of the power combined with the interest of the original cost of the line, and that the calculation of this combined expense must form the element of comparison between different lines of railway.

CORROSION OF IRON IN STEAM BOILERS AND STOVE PIPES.

(From the Franklin Journal.)

The Committee on Science and the Arts, constituted by the Franklin Institute of the State of Pennsylvania, for the promotion of the Mechanic Arts, to whom was referred for examination the Corrosion of Iron in Steam Boilers and Stove Pipes, where Anthracite is employed as fuel, REPORT:—

That they have gathered such information as lay in their power from those who have witnessed the corrosive action, and combined it with their own observations.

It appears that stove-pipes are frequently corroded in the course of a year or two, where they are not taken down or cleansed subsequent to their employment through the winter season. An instance is known in which 40 ft. of pipe were corroded and rendered a perfect colander in the course of two years. Nor does it appear always as a necessary condition that the place should be damp, although this is the case in a majority of instances, for in the corrosion just noticed, the proprietor stated that the stove was very dry. The corrosion rarely happens in an upright pipe, but usually in one lying horizontally, for where such corrosion had already commenced it was said, in one instance, to have been obviated by giving the pipe a slight inclination. Where it takes place in an upright pipe, it may arise from the flowing down of corroding matter from a horizontal layer of the same.

The same kind of corrosion is observable in steam boilers in which anthracite is employed as fuel, and not in those in which bituminous coal is used. That it does not arise from the intensity of the heat is shown from the fact, that it is greatest in the boiler-flues which lie horizontally at a distance from the fire. A corrosion is sometimes observed near the top of the smoke pipe in steamboats, but this may be attributed to the alternate action of heat, cold, air, and moisture.

It would appear then, that the corrosion is caused either by the vapours arising from the combustion of anthracite, or from matter carried up mechanically by the draft; or from both combined. That it does not proceed from uncondensable gaseous matter is proved by the occurrence of the corrosion only when a stove-pipe is no longer exposed to these vapours during the summer season, or where a boiler is cooled from intermitted fires. It does not arise from matter carried up mechanically, for this could only be ashes, and we know that the ashes of anthracite are of a dry nature; and without moisture, chemical action, or the corrosion, could not occur. It must, therefore, be produced from condensable vapours.

On examining the interior of a stove-pipe lying horizontally, whether corroded or not, we find a loose ashy deposit of a greyish brown colour; and where corrosion has taken place, the greater part is condensed into a solid mass, showing that it had absorbed water. Upon fracturing the solid material, small white crystals appear under the microscope, which are generally too imperfect to admit of recognising their form. By subliming the mass, a little empyreumatic oil and water are formed, but the greater part sublimed is an ammoniacal salt. Upon testing a solution of the ashes, it shows a large content of muriate and sulphate of ammonia, the former evidently in much greater quantity than the sulphate. After complete sublimation at a red heat, the ashy matter remaining appears to be nearly pure charcoal or lamp black, with a mere trace of coal ashes. From the qualitative tests made, it would appear that the ammoniacal salts constitute at least three-fourths of the whole mass. A mere trace of iron was detected.

From this content of saline matter, as well as from its nature, we are at no loss to account for the corrosion of iron where the air and moisture add their conjoint action; but it may be doubted whether the ashy matter has the power of absorbing moisture from an atmosphere of ordinary dryness, for in dry situations, it appears that there is usually no corrosion, and in the case noticed at the commencement of the report, it may be doubted whether the stove was dry.

How to obviate the corrosive action is a more difficult point to determine, unless the very simple process be resorted to of cleaning out stove-pipes every spring, and boiler-flues every few weeks. If the stove-pipes are required to remain standing with the sediment in them, then a previous internal coating of white lead, litharge, or red lead might probably answer the best purpose, since it would result in the production of chloride and sulphate of lead, while the ammonia would be driven off. The thin coating of these salts of lead might then prevent the contact and farther action of the ashy deposit. Experiments made at the U. S. Mint during the winter of 40-41, seem to show that a coating of lime on the interior of a pipe prevents corrosion, and it is said that a few stove manufacturers in this city are acquainted with the fact. The committee, however, in the face of these facts, are rather inclined to believe that the oxide of lead will prove more efficient, since the sulphate of lead is a wholly inert salt, and the chloride nearly insoluble, while the sulphate of lime is somewhat soluble, and the chloride of calcium very soluble, and therefore likely to produce corrosive action eventually. Still the operation of whitewashing is the simplest mode of obviating corrosion, and may be repeated at intervals.

The content of chlorine to such an extent as is developed by the above chemical examination, is interesting in a geological point of view, since it has not hitherto been found in chemical examinations of anthracite. Prof. H. D. Rogers, in 1836, pointed out the fact, that where heaps of refuse

matter were burned near the coal mines, ammoniacal salts, and among them muriate of ammonia, are sublimed, and may be found among the ashes. Now we know that saline waters are obtained from the coal measures in the western district of Pennsylvania, and, moreover, it is the prevailing opinion among geologists that the coal series are marine deposits; we can, therefore, explain the origin of the muriate of ammonia in the ashy deposit arising from the combustion of anthracite, by attributing the chlorine to the presence of a trace of chloride of sodium (common salt) in the coal or its accompanying slate, or possibly in both. It is unnecessary to allude to the formation of ammonia, since it is a universal product to a greater or less extent of the dry distillation or combustion of every kind of coal.

This ammoniacal deposit is interesting in an economical point of view, since it accumulates in considerable quantity in a single season, and may be collected with facility. In one instance at least, ten pounds were removed from about eight to ten feet of pipe, which was the produce of three or four years, and hence, we may estimate the large amount that might be obtained from many hundred pipes in Philadelphia every season. It may be employed either for the manufacture of sal ammoniac by a very simple process of sublimation with a small quantity of a salt of lime, or it may be directly applied in powder or in solution to garden soils. The influence of ammoniacal salts in promoting luxuriant vegetation has long been known, but the admirable work of Prof. Liebig on Agricultural Chemistry has more completely developed their influence and importance. The material before us will unquestionably prove of great value to the gardener and florist, if properly applied to the soil; but it must not be forgotten that it is very rich in ammonia, and should therefore be employed sparingly.

By order of the Committee,

March 1.—WILLIAM CUBITT, V.P., in the Chair.

"Holborn Hill, and the Plans for its Improvement." By John Turner.

This communication chiefly consists of an examination of the various plans which have been suggested for diminishing the acclivity of that crowded thoroughfare. An idea of its thronged state is given from Mr. Whishaw's evidence before a Committee upon Metropolitan Improvements, in May, 1838, wherein he assumes the fair average annual amount of traffic between Fetter Lane and the Old Bailey at "20,000,000 pedestrians, 871,640 equestrians, 157,752 hackney coaches, 372,470 carts and wagons, 78,876 stages, 82,258 carriages, 135,842 omnibuses, 460,110 chaises and taxed carts, and 354,942 cabs." The necessity for ameliorating this great thoroughfare has been generally acknowledged, and great changes have been made in the locality since the rivulet called the "Old Bourne" took its course down the hill into the Fleet river, which at that time had wharfs on either side for landing goods from the barges, which came up as far as Holborn Bridge. About the year 1733 the arching over of the channel of the Fleet was commenced, and subsequently was extended to the Thames, forming at present one of the main sewers, having its outlet at Blackfriars Bridge. On arching over the Fleet the ground at the bottom of the hill was raised as much as possible; indeed all that can be done by filling up (having reference to the surrounding levels), would appear to have been done at various intervals.

The oldest plan mentioned by Mr. Turner is that by Mr. T. F. Taylor, in 1828. He proposed to divide the hill at the corner of Hatton Garden into three parts, and to continue the same up Skinner Street nearly to the Saracen's Head Inn; between these points an iron suspension bridge, with a level roadway, was to be erected wide enough to admit of two carriages abreast, leaving the footpaths and nearly all the houses undisturbed. The estimate for this plan was about £23,000.

In 1833 Mr. Turner proposed to construct a bridge or viaduct, upon arches, along the south side of Holborn Hill and Skinner Street, from Thavies Inn to Sea-coal Lane. The arches would have been available for warehouses upon the level of that half of the street which preserved its original position. On this plan it would have been necessary to take down all the houses on the south side from Shoe Lane to Farringdon Street; the others being modern, might have been raised. This plan was subsequently modified, and the width of the street increased to 70 feet, giving the viaduct 35 in breadth.

Mr. Moseley's proposition in 1833 was to fill up the valley to the height of 12 feet at Holborn Bridge, altering some of the houses at the bottom. In 1840 he further proposed to take 18 inches off the brow of Holborn Hill and 12 inches off Skinner Street, which, with raising the bottom, would bring the gradient of the acclivity to about 1 in 35.

Some interesting tables are given of the rates of acclivities of some of the principal thoroughfares in London.

St. James's Street, at 660 feet from Piccadilly, is	1 in 27
Waterloo Place, ending at Piccadilly	1 " 25
Haymarket, at 490 feet from ditto	1 " 22
Strand, opposite Northumberland House	1 " 33
Charing Cross, from ditto towards Whitehall	1 " 37
Southampton Street, from the Strand	1 " 19
Fleet Street, opposite Salisbury Court	1 " 42½
Ludgate Hill, ending at St. Paul's Churchyard	1 " 25
Holborn Hill, varies from	1 in 16½ to
Skinner Street, varies from	1 in 24 to 1 " 29

Messrs. Barnard and Geary published a plan, in 1836, for carrying a viaduct along the north side of Holborn Hill, between Hatton Garden and the upper end of Snow Hill, removing the greater portion of the houses between those points. The estimate of the expense was £350,000.

In the Second Report of the Metropolitan Improvements Committee for 1838 appeared a plan by Mr. Pocock, consisting of a viaduct on the south side of the hill, between St. Andrew's Court and Sea-coal Lane.

Mr. Galloway's plan, in 1841, was to erect in the centre of the present line of road a viaduct upon iron arches, between Hatton Garden and the Saracen's Head Inn; this viaduct was to be 30 feet wide, and used for horses and carriages only, leaving the street below as at present, only widening it where requisite.

Mr. Moon's plan, in 1841, was nearly similar to Mr. Turner's, only insisting upon a greater width of road.

Several propositions were also made for forming a new street either on the north or south side of Holborn Hill; among them are mentioned the following plans:—

Mr. Davey's, in 1833, which was to commence at Fox Court, in Gray's Inn Lane, cross Saffron Hill, and proceed, in the form of a crescent, to meet Skinner Street above Snow Hill.

Mr. Whishaw's plan, in 1835, was to build a viaduct, commencing at the end of Fetter Lane, to the north of New Street Square, thence across Farringdon Market, which he proposed to render more convenient and airy, and to terminate at the top of the Old Bailey, the roadway throughout being perfectly level.

Mr. Ross's plan resembled Mr. Whishaw's, but was less comprehensive, and avoided Farringdon Market, the viaduct being still nearly level.

These latter plans were laid out with a view of avoiding the existing thoroughfare, and the valuable property on Holborn Hill and Skinner Street. The plans were collected by the author for the purpose of showing their comparative merit and originality, and (as far as he was able) the dates. The communication was illustrated by a series of drawings and lithographs of almost all the schemes, with prospectuses of nearly all for reference.

March 1.—The PRESIDENT in the Chair.

"Description of the Permanent Way of the South-eastern Railway." By John Pope, Grad. Inst. C. E.

This communication commences with a general description of the slopes of the cuttings and the embankments of the line, and explains the mode of ballasting and the quality of the materials employed. On either side of the bank of ballast, and below the level of its bed, there is an open drain, 3 feet in width, extending throughout the line, which ensures perfect drainage from beneath the sleepers. The different works connected with the laying of the rails are then successively noticed. The sleepers are placed transversely, and differ in shape from any hitherto employed. They are of Baltic fir, and are formed by a square balk being diagonally divided so as to cut out four triangular sleepers, which are laid with the right angle C downwards, which

Square balk divided to form four sleepers.

Triangular sleeper A, B, C, contrasted with a half balk.

form (A B C) has as much bearing surface as one of twice the cubic content cut out as a half balk in the usual manner. The advantages arising from this form in the economy of timber, the facility of packing, and the improved drainage of the ballast in contact with the sleepers, are pointed out, and the apparent disadvantage of the tendency to act as a wedge, is combated by showing that the inclination of a right angle exceeds the limits within which the principle of the wedge obtains. The chairs are of a peculiar form, designed by the engineer to combine lightness with strength; they are cast on a plan invented and patented by Messrs. Ransome and May, of Ipswich, whereby the inward inclination of the rails, instead of being made to depend merely upon the rail layers (as is usually the case), is effected entirely by the shape of the cavities of the chairs, which are all cast with peculiar accuracy.

Elevation of Chair, showing the inclination of the Rail.

The uniformity of inclination attained by this improvement greatly diminishes the lateral motion of the carriages, observed on almost all other lines of railway. The chairs are placed horizontally on the sleepers, and are fastened down with trenails of oak compressed by the patent process of Messrs. Ransome and May.* The wedges employed to secure the rails in the chairs are similarly compressed. Details are then given of the rails, which are parallel, with their upper and lower tables of equal breadth; of the amount of compression of the wedges and trenails, their dimensions, shapes, &c.

The author concludes by stating, upon the authority of Mr. Barlow, the resident engineer of that part of the line, that the passage of 70,000 tons of ballast over several miles of the "permanent way" already completed, has not rendered the slightest repair necessary, although the weather has been very unfavourable.

The paper is accompanied by a drawing showing the construction of the permanent way, and it was illustrated by the exhibition of a pair of sleepers with two pieces of the rails placed in the chairs, which were fixed down with the compressed trenails, complete as on the railway; all the tools employed in laying the permanent line; and specimens of teak, oak, mahogany, hornbeam, walnut, and other timber, compressed and cut so as to show the subsequent form of the sap vessels.

Plan

Remarks.—In answer to questions as to the compressed fastenings, Mr. May explained that the peculiarity of the system consisted in the fibre of the timber being compressed equally from the circumference to the centre. The pieces of wood for the wedges were cut out with parallel sides and forced by hydraulic presses into tapering moulds; whilst in those moulds they were subjected to the action of heat applied through the medium of low pressure steam, and after being allowed to cool, they were forced out of the moulds, and so long as they were kept dry would retain their form; but as the operation simply contracted the dimensions of the sap vessels without crushing the fibre, the power of capillary attraction was not destroyed, and when driven into the chair and exposed to moisture, they swelled so as to remain perfectly tight. There was this difference between wedges so compressed and all others; that a true wedge was formed from a piece of wood cut parallel on all sides, whilst all former modes that he was acquainted with produced, not wedges, but parallel pieces.

* Minutes of Proceedings, 1840, p. 84.

The diminution of the bulk of the trenails, by the process, is from 100 to 63, and of the wedges from 100 to 80. It is found that the wood does not swell until it is placed in a damp situation, as in the sleepers. Even the most solid woods, such as African teak, can be compressed without sustaining injury. Perfectly seasoned timber will not shrink after compression, but green wood will shrink after the process. One of the principal advantages of the compressed trenails is the firmness with which they hold into the sleeper. Around the iron spikes generally used, a sheath of rust is formed by the damp sleeper; the shaking of the carriages tends to draw them upwards, and the elasticity of the fibre around the hole in the sleeper being impaired, it is of no use to drive them down again in the same place, and the chairs eventually become loose.

The mode of casting the chairs was described to be by placing an iron plate on each side of the pattern, ramming them up in sand, and using an iron core, which being sustained in its position by a projecting tongue falling into a groove in the side plates, preserves an uniform inclination of the rail in the chairs. Extraordinary precision is thus obtained, and only about 2 per cent. of waste-castings are made, although they are subjected to a rigid test, for if the bearing points allow the rail to vary $\frac{1}{8}$ of an inch from the required inclination, they are broken up. The iron cores do not unduly chill the metal, and the average strength is retained. The iron used is chiefly "Welsh Cold Blast."

Mr. Cubitt's object has been to lay a railway entirely upon transverse sleepers, of such a form as would expose the largest amount of bearing surface for the least portion of timber; that the bulk of the ballast should be beneath the bottom of the sleeper, where alone it is useful; to use only the best foreign timber; to have the rails rolled uniformly and sufficiently heavy;

Rails, Chairs, and Sleepers, with the "Cramp Gauge" fixed.]

Guide Tube and Auger.

the chairs simple in form, possessing great regularity, and giving the inward inclination to the rail within the chairs, instead of depending upon the rail-layer doing it in fixing them; and that the fastenings should be simple, but firm, and not liable to breakage, or to be detached by the passage of the carriages.

With these views he had directed four sleepers to be cut diagonally out of each square log of foreign timber, giving about $2\frac{1}{2}$ cubic feet to each sleeper; to place them with the right angle downwards, so that the ballast could always be consolidated by ramming, without lifting the sleeper, or digging around it, as with square, or other formed sleepers; two places are planned to receive the chairs, and one fastening hole bored in each sleeper; they are then kyanized in close tanks, completely filled with the prepared solution, under a pressure of 80 lbs. per square inch. When placed upon the ballast, the joint chairs are first put down 15 feet apart, and the intermediate chairs

loosely placed 3 feet apart; "cramp gauges," embracing the inside and outside of the rails, are then fixed between each pair of sleepers, and the wedges along one side driven up—one trenail being driven in each chair, the hole for which is previously bored in the sleeper by a gauge, to insure an equal projection on each side of the rail. A "guide tube" of an internal diameter to fit the spiral auger for boring the trenail holes, with the external lip tapered to correspond with the hole in the chair for the head of the trenail, is then used, and by its agency the holes are pierced with great accuracy, concentric with the hole in the chair, at the same time protecting the tool from being injured by the cast iron. The intermediate chairs are then fixed in the same manner, and the operations are repeated for the opposite rails; the ballast is then consolidated by ramming. It is found that the work proceeds very rapidly; the ballast supports the sleepers throughout, and has no tendency to fall away from them; the water drains away freely, and hitherto the passage of the ballast wagons over that portion of the line which is laid (although they are without springs), has been productive of benefit rather than injury.

The inclination of the rail being given in the chair had insured such accuracy, that after one day's traffic over it, the surface of the rails is rubbed equally throughout, and not alternately on either side, as is so commonly the case.

Mr. Cubitt did not claim the invention of the angular-formed sleeper, as Mr. Reynolds had used it before for his longitudinal bearing rails, but he believed that transverse sleepers of that form had not been previously laid down; nor did he claim the compressed wedges and trenails, or the peculiar mode of casting the chairs: the merit of these was entirely due to Messrs. Ransome and May, who had entered completely into his views and wishes, and executed them with extreme intelligence.

In answer to questions from the President, Mr. May replied that it had been an object to gain in the trenails and wedges the greatest amount of strength with diminished bulk, and also to cut away as little of the sleeper as possible in boring the holes; he had, therefore, introduced this method of compressing them, with a view also, that in swelling from the damp they should fix themselves tight into the soft timber sleeper, and hold the chair fast down.

He hoped to extend the use of compressed trenails to ship-building, for which they were eminently adapted; if they were used, smaller holes would be bored in the timbers, and they would hold tighter than the trenails now used, which require to have the points split and wedged up, and the heads also divided and caulked to prevent leakage through the open sap vessels of the wood.

The President remarked that on the Hull and Selby Railway, the chairs were fastened to the kyanized timber sleepers by uncompressed wooden trenails.

Mr. Cubitt was not aware of that fact; he had always found that uncompressed wedges and trenails would not hold tight. Some of the compressed trenails had been wetted by accident, and could not be afterwards driven into the holes in the chairs; they nearly resumed their original size, and then showed the marks of the turning tool upon their surfaces. In answer to a question from Mr. Parkes as to the comparative expense of laying the line, it was rather in favour of the system he had adopted, although the prices paid for the items separately, were higher than usual, but the saving in labour, and the almost total absence of waste of materials, gave the economy.

He then quoted a few of the prices paid; sleepers 6s. 6d. each (ready to lay down, including kyanizing); chairs 9l. per ton, free from faults in casting, the contractors for them replacing all that were broken in laying the line. Each joint chair, with three trenails and one wedge, 2s. 10d. Intermediate chairs, with two trenails and one wedge, 2s. 1d. each. The labour for laying the line was from 2s. to 3s. per yard running; the cost of fixing the sleepers, laying the rails, and ballasting complete, was from £1500 to £2000 per mile, including all expenses.

Mr. Macneill fully concurred in the importance of providing for clear drainage from the sleepers; and in the advantage presented by the angular form for ramming the ballast. The transverse sleepers, with such rails as had been used on the South-Eastern Railway, were preferable to a continuous bearing, as they would prevent the gauge from widening, and preserve an uniform regularity of surface, which would tend materially to diminish the oscillating motion so common on railways, and which was so destructive to the engine and the carriages; altogether this railway appeared to be the most perfect he had hitherto seen.

He was using, on the Dublin and Drogheda Railway, chairs of somewhat similar construction, with uncompressed wooden wedges and fastenings; they were very roughly cast in Scotland, with hot-blast iron, and the breakage was very great; they, however, cost less than 5l. per ton. He believed that chairs such as were cast by Ransome and May would be cheaper at 9l. per ton. The uncompressed trenails were found in many instances to become loose. In ballasting the railway, as stone was cheap, the whole surface of the line was pitched transversely with thin stones, and then a good bed of broken stone used for ballast, in the same manner as Mr. Telford had proceeded with the Holyhead Road.

Mr. William Cubitt had compressed a considerable quantity of wood wedges, by forcing them singly, by the blow of a piston, through a taper steel mould; on leaving the mould they had attained their ultimate state of compression, and they were some time before they reassumed their original bulk, but he conceived that Mr. May's plan, by which they were dried in a compressed state, enabled them to retain their form longer. He considered the systems

of preparation, and of laying the road, to be the most perfect hitherto executed.

Some years since, Mr. Horne had made a series of experiments on the form of timber beams, which presented the greatest amount of strength with the least quantity of timber; he found that a triangular beam placed with the base upwards was one-third stronger than any other form.

Mr. Colthurst inquired whether the trenails and wedges had been found to have lost strength by compressing. He imagined that they would not bear a transverse strain so well as before compression.

Mr. May replied that no experiments had been tried as to the relative transverse strength of timber before and after compression.

Mr. S. Seaward thought it was probable the timber did suffer somewhat from compression, but that did not militate against the system, as there must necessarily be an original excess of strength in the trenails, so that no inconvenience could result from the process.

The President observed that although uncompressed trenails do draw out of the stone blocks, they hold fast in wood sleepers. The round trenails used to fasten the chairs to the sleepers on the Hull and Selby Railway, were of a proper size to fit the hole in the chair, and at the end a square head was left, which held the chair down.

Mr. Cubitt had frequently seen trenails or plugs driven into stone blocks to receive the iron spikes which fastened down the chairs; he believed they had also been used for driving through the chairs into the blocks, but he was not aware that they had been used in wood sleepers until he employed them on the South-Eastern Railway.

In answer to a question from the President, Mr. Lynde explained, that upon the Hull and Selby Railway, trenails were certainly used in conjunction with wooden sleepers, a portion of them were uncompressed, but the greater part were compressed like the wedges; the latter were supplied by Mr. William Cubitt.

Mr. William Cubitt only supplied the wedges, they were compressed as he had previously explained; he believed that the trenails and wedges generally used upon the London and Birmingham, and other railways, were compressed by being driven through steel rings, by heavy mallets, or by a press; they were most frequently used in the stone blocks to receive the iron spikes.

March 8.—The President in the Chair.

"Description of the Tanks for Kyanizing the Timber for the permanent way of the Hull and Selby Railway." By John Timperley.

Upon the recommendation of Messrs. Walker and Burges, the Engineers, it was determined that the sleepers of this railway should be kyanized in close vessels, using exhaustion and pressure, instead of in the open tanks usually employed. The present communication, which includes a description of the kyanizing vessels, and an account of the various circumstances connected with the operation, commences by describing the apparatus, as shown by the accompanying drawing, to consist of two tanks, a reservoir, two force pumps, and a double air pump. The tanks are cylindrical, with flat ends, and are made of wrought iron plates, nearly half an inch in thickness; they are 70 ft. in length, and 6 ft. in diameter: at each extremity is a cast iron door, flat on the outside, and concave on the inner side, provided with balance weights for raising and lowering it. Each end is strengthened by five parallel cast iron girders, whose extremities are held by wrought iron straps rivetted on to the circumference of the tanks. Notwithstanding the great strength of these girders, several were broken by the pressure applied during the process. The vessels are lined with felt, upon which is laid a covering of close jointed fir battens, fastened with copper rivets; this precaution is necessary to prevent the mutual deterioration which would arise from the contact of the iron and corrosive sublimate. There was originally only one brass force pump, 2 in. diameter, and 6 in. stroke; this being found insufficient, another was added of 4 in. diameter, and henceforward a pressure of 100 lb. per square inch was easily obtained. The air pump is 10 in. diameter, and 15 in. stroke. Its construction is of the ordinary kind. The author gives in an appendix to the paper a minute description of the various parts of the apparatus, with the details of their dimensions and weight. The process is simple and rapid; the corrosive sublimate is first mixed with warm water in a trough, in the proportion of 1 lb. of the former to 2 gallons of the latter; the clear solution is then poured off into the reservoir, where water is added till it is diluted to the proper point, which may be ascertained by an hydrometer: a more perfect test is the action of the solution upon silver, which it turns brown at the requisite degree of saturation. The operations of exhaustion and pressure employ eight men for five hours, the whole process occupying about seven hours, during which time from 17 to 20 loads are kyanized in each tank. It is desirable that the timber should remain stacked for two or three weeks after kyanizing before it is used. It was found that about $\frac{1}{2}$ lb. of corrosive sublimate sufficed to prepare one load (50 cubic feet) of timber. About 337,000 cubic feet of timber were kyanized, the average expense of which, including part of the first cost of the tanks, was about 5d. per cubic foot. The timber was tested after the process, and it was found that the solution had penetrated to the heart of the logs.

The paper contains some interesting tables exhibiting the quantity of solution taken up by different kinds of wood with and without exhaustion; from these it appears that the saturation per cubic foot in the latter case did not exceed 2.25 lb. with specimens of Dantzic timber, whereas it ranged between 12.24 lb. and 15.25 lb. with pieces of home-grown wood. The author observes that this striking difference may be partly due to the greater

compactness of the foreign timber. Appended to this communication is a correspondence between Mr. J. G. Lynde and Mr. James Simpson relative to the best tests of the presence of corrosive sublimate, accompanied by letters from Mr. Colthurst and Dr. Reid; the former of these describes the process of kyanizing adopted on the Great Western Railway, and the latter suggests the three following tests:—1st, dilute hydro-sulphuret of ammonia; 2nd, a strong solution of potassa; dilute nitric acid and proto-muriate of tin, also gold-leaf with this solution; and 3rd, iodide of potassium. Directions are given for the application of these tests.

Mr. Lynde also mentions the use of a solution of nitric acid, and by the application of hydriodate of potash detecting the presence of mercury in a specimen taken from the heart of a log of timber 10 in. by 5 in., and 9 ft. long. He also details appearances of the destructive action of the corrosive sublimate upon the iron-work with which it came into contact, which would be prejudicial to the use of iron bolts in kyanized sleepers.

A drawing explanatory of the whole apparatus accompanied the communication.

Remarks.—In answer to questions relative to the process of exhausting the air from the receiver in which the bank-note paper was wetted at the Banks of England and Ireland previously to being printed, Mr. Oldham stated that as an experiment a packet of 1000 sheets of paper had remained a whole day in water without being wetted through: whereas by exhausting the air from the vessel containing them to a partial vacuum of 22 inches of the barometer, and admitting water, they had been perfectly saturated in five minutes; the edges of the paper in simple immersion would rot away before the mass was saturated; by the exhausting process 5,000 sheets of bank-note paper would absorb 16 lb. of water.

Mr. Simpson conceived that exhaustion would facilitate the process of kyanizing; but he believed that if time was allowed, pressure would accomplish the same end as perfectly, for he had observed that pieces of wood which had remained four or five days in a water-main under pressure had become perfectly saturated. Captain Scoresby, in his account of the whale-fishery, remarks that when a whale carries a boat down it rarely rises again: most probably because the fish plunges to such a depth that the extreme pressure water-logs the boat: instances had been known of the specific gravity of the planking being doubled by being carried down.

Mr. Newton remarked that immersion of timber in close tanks had been practised by Mr. Langton many years since for bending timber; a boiling fluid was used in the tanks, and the wood was subjected to heat for a considerable period. He had understood that Mr. Newmarch of Cheltenham was the first person who used corrosive sublimate for preserving timber, and that he had prepared and employed considerable quantities of wood. Mr. Kyan subsequently revived the system.

In Mr. Oldham's process of wetting paper, pressure was not requisite, on account of its open texture. About the year 1819, Mr. Oldham had tried the same process with perfect success for preserving meat.

Exhaustion had been tried by Mr. Harris for cleansing wool. The cops of wool were put into an exhausted receiver, a solution of an alkali was then admitted; after remaining a short time in the liquid, a sufficient quantity of diluted acid was added to neutralize the alkali, and the wool was washed out in clean water. The process succeeded perfectly, but was too expensive.

Mr. Palmer had employed the kyanizing process for large pieces of timber, for the ribs of lock gates, but had no means of ascertaining the depth to which the mercury had penetrated. The use of corrosive sublimate was first suggested by Sir H. Davy in his lectures at the Royal Institution, as a means of destroying the vegetating process in timber by the combination of the chlorine in the former with the albumen of the latter. Mr. Palmer much doubted whether the means used for exhausting the capillary tubes effected the object, unless the timber was in a dry state, and he considered it equally doubtful whether the solution could be forced to any considerable depth by compression, especially if any moisture actually filled the capillary tubes. The application of pressure in the process of salting meat suggested by Mr. Perkins many years ago, was a complete failure.

Mr. Simpson observed that in the experiments of Messrs. Donkin and Bramah pressure alone had been used, and it could easily be understood that owing to the cellular formation of meat, the pressure, instead of forcing the salt through it, caused the substance to collapse and the brine was prevented from penetrating.

Mr. Braithwaite explained that in Payne and Elmore's process, although pressure had been found indispensable, the meat was more perfectly preserved when exhaustion was also employed, therefore both were now combined.

Mr. May reverted to the subject of kyanizing timber; he believed that exhausting the air from the tanks previously to the admission of the solution was a loss of time—the fluid should be admitted first, or at least while the exhaustion was proceeding; labour and time would thus be saved, and the air would be more completely expelled from the capillary tubes before pressure was applied. It was essential that the timber should be as far as possible deprived of its sap as well as dried: as either sap or moisture appeared to prevent the proper action of the corrosive sublimate.

Mr. Cubitt regretted that experiments had not been made on the same kinds of wood both with and without exhaustion. The experiments on small pieces of foreign (Memel and Dantzic) timber with 80 lb. to 100 lb. pressure without exhaustion, showed an increase of weight of from $\frac{1}{4}$ to 2 oz. in pieces of about $\frac{1}{8}$ part the size of a sleeper, and that result agreed very nearly with his practice with sleepers of Memel and Dantzic timber, when kyanized without exhaustion under a pressure of 80 lb. to the inch; sleepers

of 24 to 24 cubic feet, gaining from 3 lb. to 5 lb. in weight by the process. No result had been given of experiments with sleepers of foreign fir timber, in which both exhaustion and pressure had been applied, but it appeared that the Scotch fir sleepers weighing 100 lb. when kyanized under exhaustion and a pressure of 100 lb. to the inch, gained 33 per cent. in weight, which was equal to 3 gallons of water being forced into less than 3 cubic feet of timber; he thought that this difference could not be all due to exhaustion, but that it must depend greatly upon the quality of the wood, because under a pressure of 100 lb. to the inch, the air contained in a tubular substance (such as fir timber) would all be compressed into about $\frac{1}{4}$ of its natural bulk without previous exhaustion, so that the difference between 5 lb. and 30 lb. forced into a sleeper, could not, he thought, be all due to exhaustion, but must depend upon other circumstances not explained in this paper.

The President thought that the greater degree of absorption by the Scotch fir might be accounted for by its open texture, whereas the foreign timber was more compact and also contained more turpentine. It might also have been wetter than the Scotch fir, which he believed had been the case.

Mr. Taylor observed that hitherto the attention of the meeting had been entirely directed to mechanical action, but that the chemical combination of the corrosive sublimate with the albumen of the wood, was the point most insisted upon by Kyan; it was supposed to be similar to the operation of tanning hides, in which the tannin of the bark combined with and saturated the animal gelatin, which would not otherwise be permeable by the fluid in which it was placed.

Lieut. Oldfield suggested that if the timber when piled in the tank was subjected to the action of heat at 212° , the moisture contained in the capillary tubes would be expelled in the form of steam, and that on the admission of the solution, the tubes would instantly be filled with it, because of the partial vacuum formed in them.

Mr. Colthurst observed with regard to the tests for ascertaining the amount of saturation of the timber, that he had tried all those described by Mr. Lynde, and had not been able to discover the presence of mercury in the heart of any of the timbers prepared for the Great Western Railway; their dimensions were 6 in. by 12 in. Dr. Faraday had, he believed, detected it by the aid of the galvanic battery in the heart of a piece of timber 2 ft. square, after simple immersion in the solution for fourteen days.

Mr. Moss had tried many experiments as to the most delicate tests for ascertaining the depth to which the mercury had penetrated: the most satisfactory test was gold-leaf, as from its strong affinity for mercury, the presence of the latter was immediately detected. The mode of proceeding was to put some fibres of the wood to be tested into a small test tube, mixed with a portion of dry carbonate of soda; then to place over, but not in contact with it, a small piece of gold-leaf, and apply heat to the bottom of the tube. If any mercury was present, in however small a quantity, the fumes would rise and discolour the gold-leaf.

Mr. W. Cubitt said that timber was at all times, more or less, charged with moisture: he had found deals, supposed to be dry, lose 10 per cent. of their weight from steam drying; it was evident that the presence of moisture in the pores of the wood must militate against the success of kyanizing by simple immersion, unless it was continued for a very long period. In close tanks, when exhaustion and pressure were resorted to, the moisture was perhaps of less importance; but still, if the sap was extracted, and the timber previously dried, the process of kyanizing would be more efficient.

Mr. S. Seaward adopted Mr. Palmer's position, as to the almost impossibility of forcing the solution through the capillary tubes of a long piece of timber, the pressure being applied equally all over the surface: he believed the present method of kyanizing to be very imperfect, and alluded to a number of sleepers so prepared for the West India Dock warehouses having been recently discovered to be decayed.

Mr. Martin confirmed this account of the decay of the sleepers: fifty out of seventy were destroyed; they had been prepared by simple immersion, and had been down about five years. He had understood that some of the wooden tanks in which the solution was kept at the Anti-Dry-Rot Company's yard were decayed.

Mr. C. May believed that the destruction of the tanks might have arisen from the constant corrosive action of the mercury, and not from decay. The capillary vessels of timber filled with air and sap, under exhaustion the air would expand and drive before it a considerable portion of the sap and moisture. In preparing the compressed trenails and wedges he used steam, and found that the pores were opened by it. He suggested that steam should be blown through the tanks until all the timber in them was raised to a certain temperature, and then by opening the communication with the reservoir the solution would rush in and fill up the vacuum.

Mr. Cowper believed that it was only necessary to bring the chlorine of the corrosive sublimate and the albumen of the timber into contact, when sufficiently dry, to insure the preservation of the wood. He had occasion to try experiments with paper pulp, and was constantly annoyed by its decaying—but the addition of a small quantity of chlorine had preserved it good for two years, and he believed that it would continue unchanged.

General Pasley confirmed the statement as to the increase of the specific gravity of timber from long immersion at considerable depths. He had found all the timber, except the mainmast, in the Royal George, at a depth of about 90 ft., water-logged. The oak timber had increased on an average more than 50 per cent. above its usual specific gravity.

Mr. F. Braithwaite remarked upon the doubt which appeared to exist

among members as to the correctness of that part of Mr. Timperley's paper where a sleeper containing 3 cubic feet of timber was reported to have increased 30 lb. in weight. Mr. Braithwaite had made some experiments, the results of which showed that a piece of Memel timber containing 533 cubic inches, and weighing when dry 9 lb. became double its weight when subjected to a pressure of about 320 lb. per square inch without previous exhaustion: the machine which he used not being provided with an air pump. A smaller piece of American pine, containing 76 cubic inches, and weighing 1 lb. 7 oz. increased in weight to 3 lb. under a similar pressure. This, he contended, established the correctness of Mr. Timperley's Report. There appeared also to be a misconception as to the amount of corrosive sublimate employed: the paper states that $\frac{1}{4}$ lb. was the quantity used for each load of timber of 50 cubic feet. He promised to make some further experiments, and report them to a future meeting.

Mr. Bull had prepared considerable quantities of boards for the Calder and Hebble Navigation, by immersing them in the solution for two or three days, which was about double the period allowed by the patentees. He had some specimens of the boards, and in almost all of them there was an appearance of decay in various stages. An oak board 1 inch thick, kyanized in 1839, had lain ever since upon the damp ground exposed to the air: the sap part was entirely decayed, but the heart remained sound; fungus was, however, growing upon it. Poplar boards, kyanized in 1838, 39, and 40, were all partially decayed; those which were not prepared, and had been exposed in the same situation for the same period, showed, however, more symptoms of decay. In preparing the timber he had always followed the instructions of the patentees, and had tested the strength of the solution with the hydrometer, but had mixed up fresh solution even more frequently than was supposed to be required. On dismantling one of the tanks for holding the solution, he found the iron-work partially destroyed and entirely covered with globules of mercury.

Mr. Thompson explained that the hydrometer was not a correct testing instrument if any vegetable matter was present in the solution; that the tanks on the premises of the Anti-Dry-Rot Company were necessarily made of unprepared timber; that the bi-chloride of mercury in solution would penetrate any length of timber, if the extremities of the sap vessels were exposed to its action, but that it would not penetrate laterally without pressure; it was not, therefore, surprising that a water-tight tank of unprepared wood should decay on the outside, even if filled with the solution. With regard to the strength of the solution, at first it was believed that 1 lb. of corrosive sublimate to 20 gallons of water was sufficiently strong, and much timber had been so prepared, but experience had since proved that the strength of the mixture should not be less than 1 lb. to 15 gallons, and he had never found any well-authenticated instance of timber decaying when it had been properly prepared at that strength: as much as 1 in 9 was not unfrequently used. In a cubic foot of wood prepared under a pressure of 70 lb. per square inch, mercury had been found by the galvanic battery to have penetrated to the heart.

Mr. Horne mentioned that a new process had been invented by Mr. Payne for rendering timber proof against dry or wet rot, and the ravages of insects; for increasing its durability and rendering it incapable of combustion. The mode of proceeding was to impregnate the wood with metallic oxides, alkalies, or earths, as might be required, and to decompose them in the interior of the wood, forming new and insoluble compounds.

Mr. Taylor drew the attention of the meeting to a Memoir on the Preservation of Woods which had been read before the French Academy of Sciences by Dr. Boucherie. It was argued, that all the changes in wood were attributable to the soluble parts they contain, which cause fermentation and subsequent decay, or serve as food for the worms that so rapidly penetrate even the hardest woods. By analysis it was found that sound timbers contained from three to seven per cent. of soluble matter, and the decayed and worm-eaten, rarely more than one or two per cent.; since therefore the soluble matters of the wood were the causes of the changes it underwent, it became necessary for its preservation, either to abstract these soluble parts, or to render them insoluble, by introducing substances which should prevent their fermenting. This might be done by many of the metallic salts or earthy chlorides. Pyrolignite of iron was particularly recommended as being a very effective substance and cheaper than corrosive sublimate. The process was, to immerse the end of a tree, immediately after it was felled, in the solution of metallic salt, when, the vital energies not having ceased, the fluid was absorbed throughout all the pores of the tree, by a process which is termed "aspiration." The fluid had been applied in bags, to the base of the trees when in a horizontal position, or to one of the branches, or by boring holes to the heart, a few branches and a tuft of leaves being always left at the top of the principal stem. It was necessary to apply the process speedily after felling the timber, as the vigour of the absorption was found to abate rapidly after the first day, and became scarcely perceptible about the tenth day, whilst in dead wood, or where there was any accidental interruption of the flow of the sap during growth, the "aspiration" entirely failed; resinous trees absorbed less of the fluid than any other. The ends proposed to be attained by this process were chiefly—preserving from dry-rot; increasing the hardness and the elasticity; preventing the usual changes of form or splitting; reducing the inflammability and giving various colours and odours, according to the nature of the fluid absorbed.

Mr. Bethell remarked that the process described in Dr. Boucherie's pamphlet was identical with that patented by him July 11th 1838, two years

before Dr. Boucherie's was mentioned in Paris, which was in June 1840. The specification filed by Mr. Bethell stated "that trees just cut down may be rapidly impregnated with the solution of the first class, hereafter mentioned (among which is included the pyrolignite of iron) by merely placing the butt ends in tanks containing the solution, which will circulate with the sap throughout the whole tree; or it may be done by means of bags made of waterproof cloth affixed to the butt ends of the trees and then filled with the liquid."—Mr. Bethell found that some solutions were taken up more rapidly by the sap and circulated with it more freely than others, and the pyrolignite of iron seemed to answer best; he had not hitherto introduced the process in England, because it was much more expensive than the oil of tar, the pyrolignite costing from 6d. to 9d. per gallon, and the oil being delivered at 3d. per gallon.—Mr. Bethell had used similar tanks to those described in Mr. Timperley's paper for preparing wood with the oil of tar, but as the oil is very penetrating, previous exhaustion of the air had been found unnecessary, the hydrostatic power being sufficient. The mode of working the tanks was to charge them with timber, close them and fill them with the oil; a hydrostatic pressure of from 100 lbs. to 150 lbs. to the inch was applied by means of the force-pumps, and kept up for about six hours; this was sufficient to cause the wood to absorb from 35 to 40 gallons per load. By this means a charge of timber was easily prepared daily, the cost being about 14s. per load. This was the plan pursued at Manchester for the Manchester and Birmingham Railway, by Mr. Buck (upon the recommendation of Mr. Robert Stephenson), and also at Bristol and Bridgewater by Mr. Brunel. Mr. Bethell preferred egg-shaped ends for the tanks as they resist the pressure better than flat ends. The solution of corrosive sublimate used at Hull appeared to Mr. Bethell to be very weak. The advice given by Sir Humphrey Davy to the Admiralty many years since was, to use 1 lb. of corrosive sublimate dissolved in 4 gallons of water, and Mr. Kyan in the specification of his patent states that strength, but according to the paper it appeared that 45 gallons of water were used to 1 lb. of the salt instead of 4 lbs.

In answer to a question from Mr. Pellatt, Mr. Bethell stated that his experiments on the use of silicate of potash or soluble glass for rendering wood unflammable were not yet concluded; he had proved its efficacy in this point—that as soon as the prepared timber was heated, the glass melted and formed a filmy covering over the surface, which protected it from the oxygen of the air and prevented its catching fire. The silicate also hardened the wood and rendered it more durable. This process was included in his patent of July 11, 1838.

Professor Brande could add but little to what had been said on the subject, but he mentioned a curious appearance in a beech tree in Sir John Sebright's park in Hertfordshire, which, on being cut down, was found perfectly black all up the heart. On examination, it was discovered that the tree had grown upon a mass of iron scoræ from an ancient furnace, and the wood had absorbed the salt of iron exactly in the same manner as had been described in the new process. The degrees of absorption of various solutions by different woods demanded careful experiments, as some curious results would be obtained; it was a question whether a solution of corrosive sublimate in turpentine, or in oil of coal tar would not be advantageous, as both substances were so readily absorbed by timber.

Mr. Defries explained the construction and action of his Dry Gas Meter, which was exhibited before it was fixed in the Gallery of the Institution.

The instrument consists of a hexagonal case with three solid partitions radiating from the centre to the circumference, across each division thus formed is a flexible partition, to the centre of which is fixed a plate, connected by a lever and shafts with the valves on the top of the case; by means of a combination of levers and cranks with a worm and screw a circular motion is given to dials indicating the quantity of gas which passes through the machine.

The gas, on entering the upper chamber, passes through the valve into the first division and distends the flexible partition until the lever is carried to a certain point, when by means of the connecting shaft the inlet valve is closed, the outlet valve is opened, and the second division commences its action, which is continued by the third, thus producing an equal flow of gas, and a uniform motion is given to the counter-dials, which necessarily indicate the number of times the divisions have been inflated and emptied, and thus measure the quantity which has passed through in a given time.

The instrument which was presented to the Institution, had its sides formed of glass in order to show the action of the machinery.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

May 16.—T. L. DONALDSON, Esq., V. P., in the chair.

A paper was read by Prof. Willis, "On Gothic Tracery, exemplified by the Windows of the Chapter House at Salisbury."

In the tracery of the Gothic style, four principles may be discerned, which will be found universal when the tracery is perfectly developed. 1st, Foliation, or the decoration of the compartments with those curves and points which have been denominated cusps; 2nd, Subordination, or the division of the design into certain leading compartments, which are marked by bolder

lines of moulding than the secondary compartments inclosed within them; 3rd, Parallelism, with relation to the mouldings, or groups of mouldings, which form the common divisions between adjoining compartments; 4th, Symmetry, or a similarity between the opposite sides of those divisions. In complete tracery, where all these four principles are carried out, the compartments are compactly fitted together, and the mouldings mitre wherever they meet. In the tracery of the early Gothic, these principles are only partially developed; thus, in the triforium of Salisbury Cathedral, we find foliation and subordination, but neither parallelism nor symmetry. A segmental arch incloses two pointed arches, and each pointed arch two others. Here we have subordination, and foliation appears in the arches last mentioned, and in the openings in the spandrels; but there is no parallelism, the forms of the open compartments being without reference to each other, and having blank spaces without tracery between; and symmetry is wanting, since the mouldings of the secondary and tertiary compartments are treated differently in different parts of the composition. All this is characteristic of early Gothic tracery, and may be seen at Ely, Gloucester, and other edifices in the same style. The tracery of the cloister and chapter-house at Salisbury, the details of which Prof. Willis illustrated by several elaborate drawings, is remarkable as forming a link between the early and late tracery, going a step in advance of the former, without being complete. Parallelism is added to the two first principles, but symmetry is still wanting, each corresponding set of compartments being treated differently on each side of the dividing mouldings. There is, therefore, very little mitring, although the compartments fit together perfectly, without any blanks between them, as in the triforium of the church. So great an independence in the mouldings, where the principles of tracery are otherwise so perfectly developed, is very singular. The same observations apply both to the inside and outside of the windows, although these also differ from each other.

Another characteristic of early tracery is, that every compartment, principal or subordinate, has its separate hood-mould, as in the triforium already cited; but in the cloister and chapter-house this is discontinued, and its place supplied by a large double ogee. The Professor then made some remarks on the necessity of studying the true forms of the mouldings in Gothic architecture. The ancient details will be found, on examination, to be drawn with astonishing spirit and freedom of hand, whereas it is too much the modern practice to draw all the curves with the compasses—a method totally destructive of their real character, especially in the early Gothic style. In conclusion, he exhibited an instrument by which such curves may be traced with precision. It consists of a *stylus*, bent at one end in such a manner, that while by turning it in different directions, it enters into the deepest hollows, the point is always in one axis, at the extremity of which a pencil traces the lines followed by the point. This portion of the instrument was invented and exhibited at the Institute by Prof. Willis some time since, and he has now added to it a parallel movement attached to a drawing-board: by this contrivance, the most intricate combinations of mouldings may be traced with great facility and the most perfect accuracy.

GERISH'S PATENT CYLINDRICAL MORTICE LOCK.

This lock, as shown in the annexed engraving, which is drawn to half the real size, merits general attention from the simplicity of construction, and the easy manner in which it can be fixed to doors, the portability of the key, and the security it affords. It will be seen that by merely boring a hole with an auger in the door, it is at once fixed, thereby saving considerable time in cutting a large mortice which frequently injures the door. There is only one bolt, for the purpose of locking it; there is a contrivance at the back or end of the bolt; by turning the key a lever or tumbler is let down which prevents the latch bolt being turned back. The mortice lock before us, strong enough for a room door, is 6 inches long and $\frac{1}{2}$ of an inch in diameter.

THE NEW PALACE OF MOORSHEDABAD, IN BENGAL,

Erected for His Highness Nuwab Nazim, by Major General M'Leod.

Sir—Under this head, in the number for the present month of your very valuable Journal, honourable mention is made of "Two very splendid water-colour drawings by Mr. John Edward Jones, being perspective views of a Palace built in India for one of the subsidiary princes." As the mistake into which you have most unaccountably fallen in the above notice is calculated to do me some injury both in my professional and private capacity, you will excuse me for troubling you with a few lines on the subject.

The drawings adverted to were sent to the Institution of Civil Engineers from the office of Mr. J. E. Jones by whom I was engaged to prepare them, but not one line was drawn nor one brush of colour applied by Mr. Jones to either. The work, whatever it may be, was wholly mine—drawn from plans supplied by and directions and explanations given to me, from time to time, by General M'Leod personally, who has permitted me to refer to him for the accuracy of this statement.

As I was fully prepared to bear any blame or criticism to which these exhibitions before such competent judges might have subjected me, I shall not, I presume, be considered unreasonable in claiming any credit which these productions of my pencil may be deemed worthy.

The following extracts from a letter of a much respected and valued friend in Manchester will, however, show that I have no choice in the matter, but that I am imperatively called upon in support of my own character to make this statement—"In this month's Civil Engineer's Journal, I find an engraving of General M'Leod's palace, and great credit given to a Mr. Somebody for having made the drawings. Is this a mistake, or have you misled me?" This leads me further to observe, that I have now in the Exhibition of the Royal Academy two other drawings (Nos. 1027 and 1050) from the same subject, and though not copies of those sent to "the Institution," they are composed and drawn from the same source. The two sets of drawings will be seen by many of the same individuals, and it might be imagined without some explanation, that I had been guilty of plagiarism, and had pirated both ideas and subjects from those first exhibited as the production of Mr. J. E. Jones. As this would stamp me with a character which I, in common with every honourable mind, despise and detest, I must beg of you to give insertion to this communication in your next number.

Rutland Cottage,
John Street, Hampstead,
May 9, 1842.

I am, Sir,
Your obedient servant,
J. W. ATKINSON.

Sir—I have seen and have been much gratified by your notice of the Moorshedabad palace in your excellent Journal for this month, or rather that you have thought it worthy of a place there. Mr. Jones' draughtsman has, however, made one or two unfortunate mistakes in the drawings, which I should be very glad if you could oblige me by in any way bringing to the notice of those who look upon such matters with interest, in your next monthly publication.

In the first place, the scale for the elevation is just half what it should be, the whole space from 0 to 50 being divided into 50 instead of 100 feet. In the next place he has been guilty of an omission in the plan, which I dare say you will agree with me in considering in a great measure destructive of the beauty of the southern portico, by leaving out the two internal columns between the ante of the recess, as shown in the annexed engraving; they being a principal feature in the composition, while the capitals of the pilasters or ante are very clumsily represented.

There are also one or two errors of the press in the original report, which I ought to have marked before I sent it to you through Mr. Jones. In describing the circular room, p. 152, column 2, line 48, it mentions four large covered recesses instead of *coved* recesses, and at the same place the words "over which are long panels," ought to have been within brackets [], without which that which follows appears nonsense. There also appears the word *bricken-edge* instead of *brick-on-edge*.

229, Regent Street,
May 9, 1842.

I remain,
Yours very faithfully,
D. M'Leod.

TREWHITT'S APPARATUS FOR DISCONNECTING PADDLE WHEELS.

Sir—In a recent number of your Journal, I observed a drawing and description of Trewhitt's Patent Apparatus for disconnecting the paddle wheels of steam vessels from the engines.

This apparatus has been applied by Scott, Sinclair & Co. to the steam ship Phoenix, which they have just completed, and the result of the trials made with it is so satisfactory, I consider it due to the Patentee to state that for its simplicity, facility of operation, and absence of liability to derangement, it has not been surpassed by any invention yet introduced for that purpose.

The paddle wheels are connected to, or disconnected from the engines with a friction strap by a few blows of a sledge hammer on the end of a key, which is shown in your drawing; and the greatest proof of its superiority over every other mode is that the paddle wheels were connected and disconnected when the vessel was at full speed.

Your obedient servant,

JAMES M. SCOTT.

Grenoch Foundry, May 21, 1842.

REVIEWS.

A Treatise on Land Surveying and Levelling. By HENRY JAMES CASTLE, D.P.S. London: Simpkin and Marshall, 1842.

Practical Geology. By BUTLER WILLIAMS, C.E., F.G.S. London: Parker, 1842.

Course of Civil Engineering, comprising Plane Trigonometry, Surveying and Levelling. By JOHN GREGORY, Esq., C.E. Dublin: Samuel J. Machen, 1842.

If all the books that have been written on the subject of surveying had in reality been what the authors professed, and what the public had a right to expect they should be, what a nation of surveyors would this have been! Surely no other profession in the world has ever been so blessed with the labours of industrious authors;—no other profession can boast of an amount of printed paper devoted to its especial use, which, had it been properly employed, would have sufficed to teach the art of surveying to every man, woman and child in the empire. But when we ask the question how many of these books have been worth the labour bestowed in writing them, or rather in copying and compiling them, how many have repaid the trouble of reading, and been worth the expense of buying—one general expression of indignant contempt for the stale and childish nonsense with which the majority of these books have been filled, flashes upon us from every side, an answer too correct for refutation, too bitter for ridicule.

The proof indeed that these books, in common with other means more likely to succeed, have failed entirely in that which the authors sought to accomplish, may be found in the fact that a large number of the provincial surveyors of this country are exceedingly incompetent to conduct even the process of common land measuring, on any thing like an extensive scale. The great survey which has been for some years in progress for the combined object of effecting the commutation of tithes, and the establishment of a new parochial assessment has tested in a remarkable degree the capacity of the local surveyors in all parts of the country. It would be interesting to know, with respect to each county of England and Wales, how many of its parishes or townships have been surveyed by men locally established, and how many have been done by surveyors from the sister isle, who have continued to swarm over to this country ever since the commencement of these surveys. It would probably be found that those counties where a great number of enclosure acts have been obtained within the last 50 years—those which have been the site of large engineering works, and particularly those which contain the vast tracts of land brought into cultivation by lowering the outfalls of the Ouse and the Nene, do possess at this time local surveyors who understand their business, and who would have been capable, had they been sufficiently numerous, to conduct the whole of the tithe and poor law surveys of this country. On the other hand, in those counties where there have been no waste lands or no open fields to enclose and to allot—where the development of manufacturing resources has not so extensively nor so rapidly called for the interchange and alienation of land—and where no new creation of the solid acres has required allotments, divisions and subdivisions to be made, it is quite natural to suppose that the art of surveying should have fallen off for mere want of practice on the part of its professors.

The deficiency of good surveyors in England was readily supplied from that large body whom, the Ordnance survey of Ireland had trained up in the style of practice, which was [of all others the best adapted for the ordinary chain surveys of land. A great proportion of the parochial surveys throughout England and Wales has accordingly been executed by these men, and it is impossible to deny that their productions reflect great credit upon the school in which they were trained, and upon the system which they had been taught to practice.

We are not able to decide whether all the objects required by the New Poor Law Act, and by that for the Commutation of Tithes have been thus as satisfactorily accomplished as if the survey had been executed by the native surveyors, whose local knowledge, one might suppose, would in many respects have given them great advantages over a body of strangers. But however this may be, the surveyors of England have only to thank themselves for all the injury which many of them in no very measured terms impute to the immigration of their Irish brethren. It is quite certain that if the native surveyors in England had been competent themselves to execute these parochial surveys with the necessary degree of accuracy, the value of the surveyor's labour would not at this day have been reduced to the pitiful rates at which it is now performed. Competition, in its proper place and under certain necessary restrictions, is a very good and wholesome check upon arbitrary and extravagant charges, but there are circumstances connected with the competition to which these parochial surveys have given rise, which press with peculiar hardship upon the surveyors of this country.

Admitting the truth of these remarks, it would appear that the surveyors as a body have yet much to learn; and in so far the publication of books to teach them their business seems to be justified by the necessities of the case. The misfortune however is that books may be either useful or useless, and if the majority of surveying books have been of the latter class, it would have been better by far if they had never been given to the world. But in addition to the assistance which many professed surveyors might derive from useful practical works, the instruction of the rising generation claims particular attention. The establishment of numerous colleges and schools of civil engineering, and the appointment in these of professors of geodesy and land surveying, mark well the general importance attached to the education of the engineer in that part of his profession which relates to the measuring of land, and to the other operations necessary before the commencement of constructive works.

Notwithstanding the great number of books which profess to treat on surveying, there are few which comprise any thing like a course of instruction in field engineering; and it is to supply this deficiency that the professors of this art in several of the new colleges have prepared for the use of their pupils, treatises intended to guide and promote their studies. The three books mentioned at the head of this article proceed from three of these professors, the author of the first being the lecturer on practical surveying and levelling to King's College, London, while Mr. Williams is the professor of geodesy in the College for Civil Engineers, London, and Mr. Gregory is the resident director of the College for Civil Engineering, Mining, and Agriculture in Ireland.

It gives us great pleasure to be able to speak in terms of unqualified praise of Mr. Williams' book, which not only contains a mass of condensed and useful instruction on those branches of the subject which had been treated by former authors, but also presents several chapters of great practical value upon subjects which have hitherto been quite untouched. The chapter on hill drawing and that on surveying as applicable to the colonies are of this kind. The first is an admirable description of the system of normal contours adopted on the Ordnance survey of Ireland, and on the French *cadastral* survey. It is scarcely possible to convey a clear idea of this system without quoting the entire chapter, but in its application to the representation on a plane surface of the natural irregularities of a country, it may be understood by conceiving a number of perfectly horizontal lines to be traced around a hill, and afterwards transferred to the paper on which the plan of the hill is represented. These lines are termed normal contours, and supposing the hill to be of a perfectly conical shape, they would appear on the plan as concentric circles, whilst in hills of other shapes, the irregularly projecting parts would be shown by outward flexures of the normal contours, and the irregularly retreating parts by inward flexures of the contours. The practice is to trace these horizontal lines at equal vertical distances so that the steepness of the slope at any particular point on the plan is indicated by the distance between the normal contours at that point.

"On the Irish survey, the plans with the normal contours traced upon them are afterwards placed in the hands of field-parties, whose duty consists in filling in the detail to produce physical relief, and give expression of form and character to the drawings." There is ob-

viously no limit to the degree of fidelity and value which may be given to these representations. The contours for example may be traced at very small vertical equal distances by means of levelling a series of pickets in the same way as level stakes are fixed in railway and canal works, and as the horizontal distance between the contours may always be taken from the plan, and the vertical distance being constant is always known, it is obvious that a section exhibiting the levels of the country may be laid down in any direction from a plan distinguished by this method of representing its irregularities. We have thus merely glanced at this beautiful style of representation, but we must refer our readers to the work itself for a clear and well written description of the best method of executing it in the actual practice of surveying.

The chapter on surveying as applicable to the colonies will be highly interesting at this time when so many young men are looking forward to the employment of their abilities in this distant field.

It is proposed to divide the land into sections of 80 acres, comprised in rectangles, whose length is equal to twice their breadth, and of which there would of course be eight in a square mile. But as in all new countries the possession of water frontage is considered a great advantage, some contrivance is necessary to distribute this in an equitable manner, and to overcome the irregularity which would be introduced into the form of the allotments if those bordering on the rivers were made of equal size with the others. This contrivance appears admirably adapted to afford satisfaction to the purchasers of the sections, and to preserve uniformity and simplicity in the method of laying them out. It is impossible however to describe it without the aid of the diagrams which illustrate this part of the work. The author states that he is "indebted for the information embodied in this chapter, to the able report on *surveying as applicable to the colonies*, made by Captain Dawson, R.E. to the Secretary of State for the Colonies, in 1840." It were well if this gentlemanly habit of acknowledging the sources of information, which Mr. Williams has every where followed in his book, could by some means or other be made to possess more favour in the eyes of authors. There is one admirable feature also in Mr. Williams' book which we must not omit to notice, namely, that all the lumber about practical geometry and trigonometry with which most of the surveying books are half filled has been discarded, and he commences the book in a plain straight forward way, by showing how to survey with the chain. When youths are set to learn even the elementary parts of mathematics, such as geometry and trigonometry, it is not usual to put into their hands books on surveying for this purpose, and we have always been at a loss to understand for whose benefit—unless for that of the printer and the paper merchant—so great a quantity of elementary instruction in mathematics has preceded the introduction of the real subject of the work. In addition to the two chapters we have noticed, Mr. Williams' book contains excellent remarks and instruction on the following amongst other subjects—levelling with the mountain barometer—mining surveys—latitude and longitude—maritime surveying, the whole of which are treated in that masterly and original style which indicates a perfect command of the subject in all its branches.

Of the other two books before us we have little to say. A single glance suffices to show that they are not the productions of practical men. They abound in most of the faults from which Mr. Williams' book is free. Abundantly prefaced by preliminary matter which may be taken from any elementary course of mathematics, they have both scrupulously followed the practice of those venerable and ancient authors who wrote on surveying 100 years ago. Thus the pupil is first taught to survey one field by itself, then two fields together, and then a bolder spring is taken, and he may proceed to half a dozen or to a large survey. All this is mere nonsense, because the principle on which land is measured, particularly by the chain, is so perfectly simple that it is just as easy to practice upon 500 fields together as upon one, two, or three. It will scarcely be believed that the examples showing the method of surveying even these single fields are such as any schoolboy, or at least any lad who has had three days' instruction in the field, would be utterly ashamed of.

What will the practical surveyor say to such notes as this taken from the example of a field book by Mr. Castle, for a survey of fields near Maiden Lane. Line 578 ends at offset 98, at 908 on 1728. Line 579 ends at offset 23, at 820 on 1955. Line 734 ends at offset 21, at 483 on 968. We could scarcely believe, even on the actual evidence of our eyes, that the author meant these lines to terminate not in other lines but at loose points determined by offsets. There is however no doubt of the fact, because the plan showing the construction lines quite confirms it. To those of our readers who have ever paid any attention to the subject, no comment can be necessary on such a specimen of surveying as this.

Both the works are full of those old woodcuts which adorn the sur-

veying books written by our ancestors, and they both contain the same ample variety of expedients for doing that which no one was ever puzzled to do, and probably will never be required to do if he should practice surveying for 100 years. To give an idea of the extent to which the most approved system of bookmaking has been followed by Mr. Gregory, we may state that out of the 300 pages which compose the book, the first 160 are filled with a treatise on logarithms and plane trigonometry, and with tables of logarithms and sines and tangents, which tables to the amount of 50 pages being duly set forth in the middle of the book, produce the agreeable effect of varying the monotony of the letter-press, at the same time that they serve to eke out the contents of the book to a very respectable bulk. This work of Mr. Gregory's is called a course of civil engineering, and this is the first volume of it. None of this relates to engineering, but one may anticipate, from the specimen before us, what a splendid contribution to engineering science the succeeding volumes will constitute.

Lecture on Fresco Painting. By Mr. HAYDON. London: H. Hooper, 1842.

Among the labourers in introducing fresco, Mr. Haydon has taken a prominent position, and we hope will do much good. We are pained to see that he is no longer what he was, for though occasionally breaking out against "cocked hats," and the detestable Academy, his opposition is more tempered, and his exertions better directed. As a lecturer on the arts, he has done more than any man of the day in making them popular, his address is striking, his mode of treating his subject pleasing, his acquaintance with his subject extensive, and his teachings, if not always sound, erring only by aiming at an unattainable standard. As a public man, Mr. Haydon is now in the third act of his career; his first was that of the promising artist, his second that of the embittered, disappointed, and overweening opponent of the whole artistic community; in his third act, as a public teacher, he has given a popularity to art by lectures both in the metropolis and the provinces, which have not only led to the formation of many schools of design and classes for drawing, but have raised the character of the artist and the artisan. After exhibiting at the British Artists' Institution last year, and the Royal Academy this, and having seen that both now and on some former occasions, he could deliver an hour's discourse without vituperating the "cocked hats," we look upon him as an artist restored to the world, and we rejoice for him. He is now, we hope, about to do service to the public, and honour to himself, by promoting the national celebration of all the arts, which the Houses of Parliament will immortalize.

Mr. Haydon is one of the west countrymen who have given so many illustrious names to art, numbering two presidencies and the triumphs of Reynolds, Lawrence, Opie and Bailly. He came up from Devonshire one of the most promising men of the day, and started with Wilkie, to whom he was equal in the delineation of nature, while he was then superior in having the choice of southern instead of northern features, and having higher artistic aspirations. Wilkie's subsequent career of honour, all know. A schoolboy quarrel with the Royal Academy, one of whose members is said to have exclaimed, on hearing of the arrival of Haydon's pictures for the exhibition, "Oh! Haydon's pictures to the coal-hole," made him the Timon of modern art. Hinc illa lachrymæ. He had rivals and he had partisans, he ruled his small senate at Utica, and the class-book of human nature teaches us the result, the ruin of his social and artistic position, and the gradual narrowing of the circle of retainers, and the increase of that of foes. Even with extraordinary men, the end of this has generally been fatal; Mr. Haydon owes it to his "bona indoles" that he has survived to lead a more useful career. After being run after by the crowd, and the master of Eastlake, Lance, and many eminent men, he had almost ceased to enjoy the public countenance. He was little cared for as a martyr, and his pictures had become too academic to satisfy either his own old admirers or the public at large. Then came a change over art, partly, it must be owned, the fruit of his own exertions, the epoch of popular instruction, and he has taken a part, as we have said, in carrying out this great end, which, recalling the kindly feelings of his nature, and bringing him in close contact with the great public mind, the mother goddess, has reanimated his exertions, and directed them towards better ends, and he may rest assured that if he do but show himself worthy, he has awakened such a spirit as will allow no faction to exclude him from public patronage, and no malignity to deprive him of his reward.

We have now to come to his doctrines. Struck with the Promethean fire of the Elgin marbles, he has for years breathed nothing but Greek art, and looking at those works as the masterpieces of the

world, he has become their secretary. He holds that high art consists in the selection of the best parts of the best models and in their union, a theory which, however specious it may be, is opposed to all natural laws. Nature always requires a balance of powers, a repose after exertion, and the practical effect of the *to kalon* principle in art has been well shown by Mr. Severn in the last and present number of the *Journal*. It is to vitiate and weaken the hand of the artist, while it produces a work which palls on the eye. We believe that it is possible to produce a greater work than the Transfiguration or the Assumption, but then it is not by going out of nature, but by availing ourselves of it. The all-exquisite, for it is not the all-beautiful, seems not to have been sanctioned by the Creator, nor to be pleasing to his creatures, and a collection of Apollos, Venuses, Theseuses and Ilissuses, are about as unpromising on canvas, as the career of a modern Adonis is represented in an annual, who, too handsome for anything, wished for the horrors of the small pox to relieve him from his splendid misery. The mind will look in the picture for what occurs in the world, and when it knows what English princes and great men are, what an English senate is, and what a mass of human beings is in any place, it cannot attach the idea of nature to the paradisaic creatures who are grouped by the academists. We may look at the Ilissus or the Apollo singly, we may bear the Graces united, but we could not interest ourselves even in the whole family of the Niobes, if they were too much above the everyday standard. It would be well for art if its professors would oftener refer to the politico-economical doctrine that to be beautiful a thing must be fitting, and we should have less of the prettiness of art. That we are very backward in drawing we know, and we are indebted to Mr. Haydon for having called public attention to this defect, but we cannot, and particularly with his own works before us, believe that the *pankalon* or rather the *partariston* is the right principle in art. To our seeming, his sketches, John Bull at Breakfast and Traveller reading the Times, contain more true art, than any of his recent grand works, and the Mock Election in the King's Bench and Chairing the Member are better worthy of immortality than his infant Mary Queen of Scots, now in the Royal Academy. How Mr. Haydon can reject David and the votaries of lower Greek sculpture on the one hand, and pin himself to elder Greek sculpture on the other, is a phenomenon we do not attempt to explain, we can only say that sculptural partisanship is equally bad whatever may be its standard. Another, but more harmless dogma of Mr. Haydon is the sovereignty of Greek painters, and he talks as confidently of Parrhasius and Polygnotus, and Apelles, as if their master works were at Hampton Court or the Stafford Gallery, and engravings of them in every parlour. That this subject is involved in uncertainty, and that not a fragment exists on which we can build up a judgment, is of course no argument against enthusiasm.

We have devoted this length to an exemplification of Mr. Haydon's views, because they are those propounded in the work before us, and because they are widely disseminated among the public, while we thought we should be rendering a greater service to our readers by warning them against Haydonism, than by giving them another dissertation on trullisatio and marmoratum. Mr. Haydon's lecture is one which the public will greedily devour; according to the modern syncretic and æsthetic phraseology, it is highly suggestive. The artistical part is good, the practical part is good, and with a "cave canem" as to Haydonism, it is all good. It breathes a manly, a kindly, and an English feeling, it reminds us of what our forefathers have done, and if Mr. Haydon and his brethren can but paint as he speaks, the second St. Stephen's shall be painted by Englishmen as the first was. As to his recommendations of painting the house with allegorical illustration of abstract principles, the Blessings of Peace, and the Horrors of Anarchy, it may please advocates of high art and metaphysics, but we would much rather see the Painting of the Potatoe, or the Triumph of Punch, than any such Bolognese and un-English performances. The allegories belong to high art, which if it recommends and executes such things, we think is deservedly named by the bulk of the artists, a great humbug. The commissioners have left in the choice of subjects from our poetry and our history abundant scope for the delineation of nature, and nature let us have.

A Catalogue of Works in all Departments of English Literature, classified with a General Alphabetical Index. By Longman & Co.

In this age of catalogues raisonnées, we suppose we must hail with pleasure any accession to the collection. Messrs. Longman's is a pretty large one, and may be advantageously consulted.

Gandy and Baud's Windsor Castle: Part VII.

As the next part of this publication will be the final one, and will contain the letter-press portion of it, we shall, after that has appeared be able to speak more fully of the work and its character. As far as we can judge in the meanwhile, we must say it appears about to be terminated somewhat abruptly, for there has not as yet been either a single section or interior view of any kind, which is all the more serious an omission, because in this respect, Messrs. G. and B. could have taken a vantage ground that had been neglected by the rival work, and given their own a superior interest, both for professional men and others. As it is, we fear we are likely to get not much more information from the two together, than from either of them separately. Whether it will be the same in regard to the letter-press remains to be seen; we can only say, we trust such will not be the case, there being very little to go over the same historical ground again, more especially as there is such an ample field open for both description and criticism, and for explanatory remark, there being very little of these latter in Mr. Poynter's essay, for that gentleman seems to have been very shy of discussing the architectural merits of Windsor Castle, as it came from the hands of Sir Jeffry Wyatville. Let Messrs. Gandy and Baud's editor make up; and if he at all understands the subject and give it proper attention, he can hardly fail to discover a great many fresh points upon which to touch, or rather, which would very well bear to be brought forward somewhat prominently. At all events, as Messrs. G. and B.'s work will be less extravagant in size, it will be a more readable volume as far as mere form goes; all the more desirable, therefore, is it that it should contain something worth reading, and be entirely free from all that 'cram,' with which those who are employed to furnish a certain quantum of letter-press to books of engravings, are generally apt to eke it out.

Elementary Perspective. By T. J. RAWLINS. London: Tilt and Bogue. 1842.

CONTAINS six plates, exhibiting a variety of diagrams both of angular and parallel perspective; it is a cheap work and is well adapted for the beginner.

A Manual of Electro-metallurgy. By GEORGE SHAW. London: R. Groombridge, 1842.

A VERY interesting little work on an important art yet in its infancy, and one that promises to be of the utmost value; consequently whatever information that is given on the subject is extremely welcome, particularly so when all the principal facts connected with the art are fully developed in such a concise manner as they are given in the book before us.

South Eastern Dover Railway—Official Map and Section.

WE have before us a most complete, cheap, and extensive map of the South Eastern District of England and part of France, showing this railway and its section, together with all the other railways, and some proposed new branches leading out and immediately connected with the undertaking. It appears to contain a mass of information; and the public, we think, are much indebted to the direction for having it prepared. We have no doubt that it will prove very valuable to all travellers living in the immediate contiguity of the line, or traversing it on their way to the continent. Indeed it is so perfect, that it ought to be possessed as an accessory to the topography of the district.

Two Essays on Radiant Heat. By THOMAS CHALMERS and DANIEL R. HALDANE, Students in Arts. Edinburgh: Maclachlan and Co., 1842.

These are Edinburgh academic essays stamped with the approval of the professor, and published for the purpose of giving a popular view of this branch of science, for which purpose we also recommend this joint contribution to the notice of the public; in doing so we cannot do better than quote the words of the Professor:—

"The clearness with which the details of this rather intricate subject have been seized by the authors, renders them, I think, highly creditable as Academical Exercises. In selecting them for publication from amongst others, also of great merit, I wished, in the first place, to mark my opinion of their value in this respect, and, at the same time, to see published in a concise and popular form a correct analysis

of experiments which have as yet been but very imperfectly described and incorporated, even in approved scientific works."

Fractional Arithmetic Reviewed and Practically Exemplified. By E. CLIFFORD. London: Simpkin and Marshall, 1842.

The doggerel on the difficulties of arithmetic is familiar to every one; according to this authority "fractions" and "distractions" are rhymes and synonyms, and certainly there is no part of arithmetic which gives more trouble to the uninitiated. This plague of fractions, both vulgar and decimal, Mr. Clifford has undertaken to mitigate, by rendering it the subject of a particular treatise, in which he has endeavoured to smooth away the difficulties.

The Question What can now be done for British Agriculture, answered in a Letter to Philip Pusey, Esq., M.P., President of the Royal Agricultural Society. By J. BAILEY DENTON, Land Agent. London: Ridgway, 1842.

Mr. Denton's answer to this question is the introduction of a general and uniform system of drainage, with a profitable distribution of the surface and drainage waters and the refuse of towns; and in the propriety of such a measure every one will concur. It suffices to say that Mr. Denton has urged on the agriculturists an important subject in an able manner. There is much however to be said on both sides, as to their salubrious effects, on account of the employment of manure in the neighbourhood of great towns.

The Cabinet Cyclopædia, a Manual of Electricity, Magnetism, and Meteorology. By DIONYSIUS LARDNER, D.C.L., F.R.S., &c., Vol. I. London: Longman and Co. 1842.

This is the first of two volumes in which Dr. Lardner proposes to treat the subject of electricity and the cognate sciences in a popular manner. The present volume takes up the elements of electro statics and dynamics, magnetism, electro-magnetism, thermo-electricity, and electrical machines. To say that this has been done in a masterly manner is scarcely necessary to those who recollect the previous volumes of the cyclopædia, and the satisfactory way in which they were executed. The next volume will treat of the applications of these sciences to the practical pursuits of life, and we anticipate for ourselves and our readers much gratification in the perusal.

A Series of Diagrams illustrative of Mechanical and Natural Philosophy, and their Practical Application. Drawn on Stone by H. CHAPMAN, and printed in colours by C. F. CHEFFINS. London: Chapman and Hall. 1842.

These splendid diagrams, the first number of which, treating on the lever, lies before us, do much credit to the patronage of the Society for the Diffusion of Useful Knowledge. They have been confided to the care of Mr. Chapman and Mr. Cheffins, who have produced designs which, to the professor and the pupil, the engineer and the workman, will be found of interest and of value. The style of the tinted lithography does Mr. Cheffins great credit.

The Grainer's Guide. By CHARLES MOXON. Edinburgh, 1842.

This is a class of works which we much wish to see extended—the class of practical works by practical men. The reasons which Mr. Moxon gives for treating upon the subject of graining and imitating marbles, we much wish that we could give at length; suffice it that by the publication of this work he has supplied a desideratum in technical literature, and rendered a great benefit to the workman. The work is a large one, and yet of a moderate price, while the specimens, which are numerous and on a considerable scale, are nearly all executed by hand. The letter-press is of course a minor feature in such a work, but the directions are sufficiently copious, while, as they emanate from a practical hand, they are calculated to be highly useful, and to abridge in many cases the labour of the workman, and so to extend the sphere of his employment. When we consider the great extent to which graining is now used and the desirableness of having well instructed workmen, we feel indebted to Mr. Moxon for his exertions, and we are sure that he will reap his reward in the patronage of his book by the public, both as a work of art, and one of practical utility.

Lectures on Architecture, with reference to the Proposed Metropolitan Music Hall. By JOSEPH HANSOM, Architect. London: Barth, 1842.

Mr. Hansom erected the Town Hall at Birmingham, which is 82 feet high to the apex of the pediment, 104 feet wide at the base, and 166 feet long; he now proposes to erect a national Music Hall for £30,000, which shall be half as large again as Westminster Hall, and be 150 feet square and 121 feet high, with a recess of 100 feet wide and high and 25 feet deep, for the organ and part of the orchestra. The orchestra is proposed to advance into the room at the base, and there occupy its whole width 150 feet; it will ascend into a slope and to an altitude which the designer compares to that of the side of a hill of considerable steepness and magnitude, manned with an army of musicians, 2500 singers and performers. The Hall is to be capable of containing 8000 persons, and even in case of need 15,000; the price of the organ, which is to be the largest in the world, is included in the estimate of £30,000. The roof Mr. Hansom proposes to construct on the principle of the suspension bridge, from the four corners of the building. The roof to be of iron, and to weigh 200 tons. The height he says is less than that of the cathedral of Amiens, which is 140 feet, of Beauvais, which is 160, and of Cologne, Milan, Strasburg and others. He further offers for £1000 to build a model Hall as large as Exeter Hall, and observes that Exeter Hall is engaged every evening till September, except Saturday, at twenty-five guineas per night. Mr. Hansom promises wonders, but he has done so well hitherto that we must not distrust his success for the future.

A Hand Book of Ornamental Mapping and Engineering Drawing. No. 3. By BENJAMIN P. WILME, C.E. and Surveyor. London: Weale, 1842.

Mr. Wilme perseveres in his labours. In the present number, one of the plates affords delineations of the several classes of timber, other various signs used in mapping, and also the method of showing strata in section, and likewise the method of delineating mountains.

First Additional Supplement to the Encyclopædia of Cottage Farm and Villa Architecture and Furniture. By J. C. LOUDON, F.L.S., &c. London: Longman and Co. 1842.

Mr. LOUDON's indefatigable exertions in the cause of making architecture popular, has induced him to continue his Encyclopædia by giving occasionally supplementary numbers, by which means he will be able to collect together a vast variety of useful domestic improvements, not only in the construction of buildings, but also in the fittings and furniture. The part before us fully testifies the utility of such a work; it is full of wood engravings of cottages, villas, inns, schools, &c.

OBITUARY.—It is with regret that we have to record the death of Mr. Samuel Seaward, who died on the 11th ult. He was one of the partners of the firm of Messrs. John and Samuel Seaward and Capel, of the Canal Iron Works, Limehouse, a member of the Royal Society, and an indefatigable member of the Institution of Civil Engineers. He devoted great attention to the construction of the steam engine, and was the patentee of several improvements, and author of a variety of papers read before the Institution of Civil Engineers, on a comparison of long and short stroke engines, auxiliary steam power applied to sailing ships, &c.

STEAM NAVIGATION.

THE STEAM SHIP "LITTLE WESTERN."

Sir,—If you peruse the article on this vessel, inserted in your excellent Journal for the present month, I have no doubt you will agree with me that it contains an assertion which is not borne out by the rest of the article; and I think that the writer, in making a public statement to her prejudice, was bound in fairness to state the grounds on which it was based. I allude to the following expression: "that there is anything either in the structure of the hull or machinery pre-eminently excellent we utterly deny. In the production of the vessel, there appears to have been too great a straining after novelty, and there are evidences of a disposition to select arrangements, not so much by the consideration of what is excellent as of what is unusual."

I know not whether so strong an expression as that which forms the first part of the above extract was called for: I can only say that I have made several trips on board the vessel, and have thus had many opportunities of seeing and conversing with several gentlemen interested in her, and I never heard them

boast of her excellence in exaggerated terms; they merely expressed their confidence of her surpassing the Herne Bay and Gravesend boats, and, as far as I have had an opportunity of judging, that confidence is by no means unfounded. On Monday last, returning from Ramsgate, the *Little Western* left the pier at Herne Bay about twenty minutes after the *City of Canterbury*, and passed her off Gravesend, which shows her speed to have exceeded that of the latter vessel in the ratio of about 8 to 7. At the Nore, the *Orwell* was quite out of sight, and we passed her with great ease near Woolwich if I recollect right. To the best of my observation, the distance from Gravesend to Blackwall was performed in five or ten minutes less time than by the *Railway*, but that boat was too far a-head to allow of any certainty in the observation. On a former occasion, I have been informed, the *Little Western* beat the *Railway* by one mile from Long Reach to Blackwall.

You will perceive that the chief part of the statements contained in this communication are made from my own observations, to which I have added some information which I obtained on board. The latter is not so ample or satisfactory as I could have wished, or might probably have been enabled to communicate, had I had the advantage of seeing Mr. Morgan himself, from whose designs and under whose inspection the vessel and machinery were constructed.

With regard to the second portion of the above extract, I have committed to paper a few remarks, which, in justice to the spirited and enterprising firm of Acraman, Morgan, and Co. by whom the *Little Western* was produced, I should be glad if you would favour them with insertion in your forthcoming number.

It is apparent that the writer of the article above alluded to had never seen the engines at work, or he would not have expressed himself so doubtfully on the subject of the air-pumps, nor have been led to assign undue importance to an evil, whose absolute existence may indeed be indicated by theory, but which the same theory more closely followed up, must have shown to exercise but a trifling, if not inappreciable influence on the result. I will not unnecessarily trespass on your valuable space, by dilating on the advantages of their construction, as the writer of the article in question was fully impressed with their value; but, with respect to the evil apprehended by him, viz., the accumulation of air beneath the plunger, I can assure you, Sir, from my own experience, that it does not exist to any serious extent, having found the vacuum in the condenser, by actual inspection of the gauge during several trips, to range from 27½ to 27¾ inches. It is clear, that there is, strictly speaking, no accumulation of air, for that would necessarily end by bringing up the engine; but, as soon as the vacuum has been formed to the degree above stated, the air pump is capable of maintaining it at that degree, by discharging all the injection and condensation water, as well as the air involved, during each revolution of the crank. I may here observe, that the vacuum is unavoidably impaired by the great velocity of the piston. This is the only part of the vessel or machinery to which, as I can make out, the writer takes exception, and that only on vague and uncertain grounds; he passes over all the other details without comment, though he praises in deservedly high terms the workmanship of the engines generally.

Now where, I would ask, is the "great straining after novelty?" I believe the only absolute novelties are the structure of the hull and the horizontal position of the cylinders as applied to beam engines.

With respect to the former, the ribs of the vessel, as stated in the articles referred to, are of T iron, and the exterior or shell consists of two-inch plank, the whole being firmly united together by means of wrought iron braces, both between and on the inner side of the two thicknesses of plank, the former being placed in one diagonal direction. The combination of strength and lightness, as well as the saving of space attained by this construction, which was designed by Mr. William Morgan, are obvious, and it cannot therefore be said to have been "selected, not so much by the consideration of what is excellent, as of what is unusual." Such an assertion would impute nothing short of insanity to Messrs. Acraman and Co., for what man in his senses would build a vessel for sale on a novel principle of construction, and by that very circumstance liable to meet with prejudice, unless he had reasonable grounds for considering the innovation as a substantial improvement?

Neither can the peculiar disposition of the engines be attributed to so absurd a motive, for I think it can be clearly shown to possess material advantages. The connecting rods can thus be made of a desirable length without raising the paddle shaft too high for the most advantageous action of the wheels, which would not have been possible if the cylinders had been vertical; and the valves can be much more conveniently placed on the upper side of the cylinders. As another advantage of this arrangement may be mentioned that the principal strain is always very nearly horizontal, and divided, through the medium of the diagonal stays, between the columns which support the shaft, and those which support the beam centres, the immediate and obvious effect of which is greater ease of motion to the vessel. The lower side of the cylinder is relieved of the weight of the piston by making the piston rod pass through a stuffing-box in the cylinder bottom.

I think I have satisfactorily shewn that the novelties introduced in the hull machinery are attended with beneficial effects, and shall now proceed to consider briefly those parts which are not new.

In the first place the boilers, which are Spiller's patent, have been long known, and have been previously used by several of our leading marine engineers, though, for my own part, I do not admire their principle, since the flame passes directly through them in a vertical direction from the furnaces to the funnel, by which I apprehend much heat must be wasted. The *Little Western's* boilers are, however, much larger than the patentee would have made them, and were made under the direction of Mr. Spiller's chief assistant, by whom the drawings had been previously approved. The steam and eduction valves, being balanced, require very much less power to work them than the slide valve generally used, and they can without inconvenience be made very large; the *Little Western's* are 14 inches in diameter. I have already disposed of the question of the air pumps. The paddle-wheels are Morgan's patent, and their superiority over all others has been successfully tested by twelve or thirteen years' experience.

I beg, in conclusion, to make the following additions and corrections in the data contained in the article above referred to. The cylinders are fifty-one inches diameter, stroke 4 ft.; air-pumps 31½ inches diameter, stroke 2 ft. 6 in.; steam pressure in the boiler 8 lbs. (on Monday last it was frequently as low as 7, and occasionally 6½ lbs., perhaps sometimes lower still), cut off generally by the expansion valve at ⅔, otherwise by the steam valve at four-fifths; power of the engines, 90 (104) horses each, with the full number of revolutions (30), but as they generally make but 28, their power is consequently reduced to 84 (98) horses each.

Hoping that the above remarks may be found worthy of attention, and may correct any erroneous impression which the article in this month's *Journal* may have produced,

I remain, Sir,
Your most obedient servant,
PIGLAETHES.

London, 24th March, 1842.

THE PRECURSOR.

In a former number we made a few remarks respecting this vessel, and we have much pleasure in reverting to the subject. The following are a few of the Precursor's dimensions:—

	Ft. In.
Diameter of cylinder	6 8
Length of stroke	7 0
Number of horses power 520 the pair (the piston travelling at 245 ft. per minute.)	
Burthen 1555 tons O.M., and 1751 tons N.M.	
Length from figure head to taffrail	281 0
Length from stem to taffrail	244 0
Length of keel and fore-rake for tonnage	232 2
Extreme breadth over paddle-boxes	81 10
Breadth on deck between paddle-boxes	37 4
Extreme breadth on deck	41 6
Depth of hold amidships	25 0
Weight of iron in bolts, knees, and fastenings	123 tons.
Weight of copper in bolts, &c.	36 "
Weight of copper sheathing, 13,000 superficial ft.	10 "
Weight of machinery, coal boxes, boilers and their water	500 "
Weight of hull	1800 "

The computed draught of water, with the full complement of stores, provisions, &c. for an East India voyage, and 960 tons of coals, is 17 ft. 8 in. forward, and the same aft. The vessel is provided with tanks for the stowage of a considerable part of the coal: when the coal stowed in these tanks has been burned, they may be filled with water, thereby preserving the proper trim of the ship, and the requisite immersion of the paddles.

The engines are very similar in their arrangement and general appearance to the engines of Messrs. Maudslay and Co., but stronger. They are a handsome and extremely substantial piece of workmanship, and there are several excellencies in their construction not always to be found in the engines of the Clyde manufacture. A few of these peculiarities we shall notice. The valve casing, instead of being bolted to the cylinder throughout its entire length, is only attached to the cylinder for a short distance at the top and bottom ports. The body of the casing forms a D-shaped pipe, and in the middle of this pipe there is a faucet joint to permit the expansion of the valve casing without occasioning fracture, flexure, or strain. Many engines are unprovided with this appliance, and in large engines the want of it sooner or later occasions serious injury. Previous to the starting of the engine, the valve casing is always hot and the cylinder always cold, and the difference of dimension consequent upon the difference of temperature must either start the joints, bend the cylinder, or tear the ports asunder.

Although the engines of this vessel are of such a large size, the valves may be moved by one hand, even when they are cold and the grease of the packing is congealed about them. This is achieved by means of a wheel like the steering wheel of a ship, which gives motion to a pinion working into a sector on the valve shaft. The eccentric rod is thrown out of gear, by means of a short lever with a roller at its upper end. The roller presses upon the under side of the eccentric rod, and lifts it sufficiently to disengage the pin of the valve shaft lever from the notch of the eccentric rod. This disengaging lever turns upon an eccentric axis, and is so adjusted that the eccentricity acts upon the pinion, which gives motion to the sector, and draws the teeth of the pinion out of the teeth of the sector when the disengaging lever is in a certain position, and that position is the one proper to the lever when the eccentric rod is in gear. By this judicious and elegant expedient the starting wheel can never be driven by the engine, for the same act which throws the engine in gear throws the starting wheel out of gear, and the engine cannot be thrown out of gear without throwing the starting wheel in gear. In most engines started by wheels this expedient is wanting, and it is really dangerous to approach them when driven by the engines at, as is inevitable, a great velocity.

It is most gratifying to find that the sole plate and condenser are cast in the same piece. The condenser is above the sole plate, and the main centre passes through it. The greater part of the joints appear to be made by the simple contact of the accurately-fitted metal surfaces, without rust, and with merely a little red lead interposed. The cylinders are provided with good large escape valves. The expansion valves are situated in the steam pipe, and appear to be of the ordinary description, with a compound cam, adjusted to several different degrees of expansion. The boilers are fired from both ends; there are four in all of nearly the usual square form, with a passage between them, through which a person may walk; each has four furnaces making 16 furnaces in all. The boilers are not nearly so high as in the Great Western, or in the West Indian mail steam packets constructed in the Thames; and they do not appear to be much if at all longer, although the engines are of considerably greater power. The paddle-wheels are of the most substantial and excellent construction of any that we have seen. Of the internal parts

of the engines, we cannot be expected to speak from our own observation, but if they are answerable to the external parts they must partake of the praise we have awarded.

If we might be permitted to make a suggestion where everything appears to have been so well managed, we should say that the boilers ought to be clothed more efficiently. The fronts of them are without clothing at all, and some of the steam pipes appear to us insufficiently covered. This is a point involving not comfort merely, but also economy of fuel, and we also consider that the wrought iron work is badly proportioned, the cross-heads are too heavy.

The cabins of this vessel are most commodiously and tastefully arranged, and especial attention has been paid to the conditions essential to ventilation, cleanliness, and comfort, in a warm climate. The beams and all the other scantlings are of such dimensions as to ensure abundant strength in every part, and the fastenings and excellent system of diagonal trussing employed are such as to unite all the parts into a rigid and substantial whole.

Steam Navigation on the Thames.—There are now 16 steam vessels running daily between Gravesend and London, the same number to Woolwich, 20 to Greenwich, numerous small steamers, the boats of the Waterman's Company, and of the Old Woolwich Company—between Greenwich and Blackwall; there are eight steam vessels constantly going up and down the river on their way to and from Dover, Ramsgate, Herne Bay, Southend, and Sheerness. The General Steam Navigation Company musters 49 steamers, all sailing from London, a fleet superior to the steam fleet of any of the continental powers, and which carry merchandise and property to the amount of £1,000,000 sterling weekly, and whose consumption of coals exceeds in value £50,000 per annum. There are not less than 50 other large steam vessels trading between London and various ports in Great Britain and Ireland; 23 steam-tugs, carrying from 30 to 100 horse power each, exclusively engaged in towing ships between Gravesend and the Pool; 20 iron and wooden steamers navigating the river above bridge, between London Bridge and Chelsea; 2 constantly running between the Adelphi Pier and Putney, and 5 to Richmond.

The Tartarus steam vessel, Commander T. W. Smith, arrived at Woolwich on Monday, April 23, from the West Indies. She has been upwards of four years in commission, traversing during that period a distance of 73,000 miles, and consuming about 5400 tons of coal, without, in a single instance, being detained one hour from service for repairs to either hull or boilers.

The Hen, Company's Steam Frigate Acbar.—On Sunday at noon, 15th ult this splendid war steamer left her anchorage at Gravesend, bearing the pendant of Commodore Pepper, of the Indian navy, who will assume the command of all the Company's ships-of-war now serving in China, under Admiral Sir W. Parker. The Acbar is a steam frigate of the first class, armed with two eight-inch guns, and four long 32-pounders, with a complement of 160 men, carrying five boats, on two of which are mounted brass 12 lb. howitzers. The engines are of the collective power of 350 horses, manufactured by Robert Napier of Glasgow, and are of a very superior description. She has four copper boilers of about seven tons each. The armoury is filled up with 100 percussion muskets, pistols, cutlasses, and musketoons, &c., the whole in beautiful order, and presenting a most warlike appearance. The Acbar carries 500 tons of coal, which, with a consumption of a ton an hour, will enable her to steam 20 successive days. She made her passage from Gravesend to Falmouth, a distance of 370 miles, in 36 hours, which gives an average speed of more than 10 miles an hour.

American Marine Engines.—We have been both astonished and gratified by the reception of a drawing sent to us from America of an excellent side lever marine engine constructed by Messrs. Stillman and Co. of New York, for two steamers built for the Spanish Government, "El Regent" and "El Congreso." It has been so much the habit of Europeans to regard the American machinery as rude and dangerous, as well as unsuited to vessels intended for the navigation of the ocean—an impression in which, to a certain extent, we ourselves participated—that this drawing has, we confess, surprised as much as it has delighted us; and it is an act of justice we feel called upon to render to say that, so far as this drawing will enable us to form an opinion, Messrs. Stillman's performance will not suffer by a comparison with the work of even the first of British manufacturers. The framing of this engine resembles the framing of Messrs. Fawcett, Caird, and Borrie, and every part of it appears to us well proportioned and arranged. The ingress and egress of the steam to and from the cylinder is regulated by spindle valves wrought by an eccentric; whether these valves are of the single or double beat description, the drawing does not specify. The eccentric rod is provided with a long nut furnished with a right-handed and a left-handed thread, so as to shorten or lengthen the rod at pleasure. There is an expansion valve of the common description situated in the steam pipe, and wrought in the usual manner. We should have been glad to have possessed more precise information respecting the interior of these engines, as for example, the nature of the piston packings of the valves, air pump buckets, as well as some particulars respecting the construction of the boiler, the consumption of fuel, and the nature of the performance as determined by the indicator. We trust we may be favoured with such details, and no efforts of ours shall be wanting to make the merits of the machinery of America as extensively known and as highly appreciated as its excellence appears to deserve.

PROGRESS OF RAILWAYS.

Railways in France.—The Chamber of Peers assembled on Monday, 9th May, in their committee rooms for the purpose of electing a committee to report on the railway bill, brought up from the Chamber of Deputies. This bill contains—first, a general classification of the lines intended to be con-

structed; second, a second system of execution, which imposes on the departments traversed by those railways the payment of two-thirds of the value of the ground to be purchased. It likewise enacts that the Government shall pay the remaining third, together with the expense of embankment, the excavations of works of art and stations, leaving the cost of fixing the rails and the material to the charge of the companies who shall undertake to complete them. Third, the allocation of funds amounting together to the sum of 126,000,000*fr.*, applicable to the following sections:—

	Francs.
From Strasburgh to Hommertin	11,500,000
" Dijon to Châlons	11,000,000
" Marseilles to Avignon	30,000,000
" Orleans to Tours	17,000,000
" Orleans to Vierzon	12,000,000
" Paris to Lille	43,000,000
For sundry expenses	1,500,000
	126,000,000

The entire plan consists of seven vast lines of the first order, setting out from Paris, and leading—1. To the Belgian frontier through Lille and Valenciennes. 2. To England by one or several points on the coast, to be hereafter determined. 3. To the German frontier, through Strasburgh. 4. To the Mediterranean, through Lyons, Marseilles, and Cette. 5. To the Spanish frontier, through Bordeaux and Bayonne. 6. To the Atlantic Ocean by Nantes. 7. To the centre of France through Vierzon, with a prolongation to be hereafter determined, with a branch to Bourges. And of two lines of the second order from frontier to frontier directed—1. From the Mediterranean to the Rhine, through Lyons, Dijon, and Melhouse. 2. From the Mediterranean to the Atlantic Ocean, through Bordeaux, Toulouse, and Cette.

NEW CHURCHES, &c.

Manchester.—On Monday, 28th March, the first stone of a new church, situate in Rodney-street, Oldham-road, was laid by Robert Gardener, Esq. This church is the fourth of those now in course of erection by the "Association for the Building and Endowing of Ten Churches in the Boroughs of Manchester and Salford." Mr. Richard Tattersall is the architect. The Norman style of architecture has been adopted, and both the exterior and interior of the building will be of a highly ornamental character. The church is in the shape of a parallelogram, whose external dimensions are about 78 feet long by 52 feet wide, with a chancel at the east end about 27 feet wide, and projecting 12 feet; at the westerly end there is also a projection about 42 feet wide, and projecting about 20 feet, which contains the entrances to the ground floor and to the galleries, as well as two staircases to the latter, betwixt which, and over the entrances, will be a recess for the organ and choir. The whole exterior of the building will be faced with stone from the Summit delphs, which is to be neatly hammer-dressed, except the ashlar dressings, which are to be neatly tooled. The westerly projection will be flanked by two turrets, terminating in pyramidal weathered pinnacles, surmounted by the old Norman cross, at a height of 66 feet above the level of the street. Betwixt the turrets there will be a boldly recessed arch, supported by small columns. The three chief compartments in the west front are surmounted by archivolt mouldings. In the west gable is a moulded opening for a clock dial, this gable terminates with coping, with chevron cut edges, sustaining a large Norman cross at the apex. Each side of the church is divided into six compartments, with a light in each; each compartment is separated by flat buttresses, terminating in moulded weatherings, and a flat segmental arch with billetted mouldings. Turned over each compartment betwixt the buttresses. The chancel stands quite distinct from the church, being roofed at a lower level, and there will be an eight light circular window in the upper part thereof, and four narrow loop lights in the lower part. The east end of the church will also have a large Norman cross on the apex of the coping thereon, and the whole is to be finished to correspond with the west gable. The recess formed at each end of the interior of the church by the projections outside, will be divided from it by large enriched arches similar to the one in the west front. Although the accommodation required, and the amount to be expended, rendered the introduction of galleries absolutely necessary, great pains have been taken to render them as little objectionable as possible; for this reason the west gallery front will not be carried more than five feet into the church, so that on entering the same nearly the whole of the interior, together with the roof, may be at once seen. On the south side of the west entrance will be the baptistry, with a Norman font, sufficiently large for immersion. In the interior of the upper part of the gable at the west end of the church there is a preparation for a clock dial, to be moved by the same works that move the dial in the west front, and which will also serve as ventilating the church; and there will be an enriched ornament in the west gable to correspond, and also for the purpose of ventilation. The church will have an open timbered roof; the tie-beams of each truss is raised up about five feet above the lower ends of the principal rafters, where they set down upon the side walls, and the space betwixt the top side of the beams and the under side of the principal rafters is divided into three compartments, by two queen posts, under which are placed enriched pinnacles, from which proceed curved and moulded ribs, and are continued over the side walls, until they set down upon the capitals of moulded pinnacles therein, the top side of the capitals being four feet below the bottom ends of the principal rafters in side walls. To avoid the danger of any lateral pressure from this form of truss, cast-iron brackets are enclosed

within the curved ribs, and are continued a sufficient distance on the tie beam, so as eventually to convey the whole weight of the roof down upon the stone corbels in the side walls, on which the cast-iron brackets are also made to set down. In the centre compartment, formed by the queen posts in each truss, will be a semicircular curved rib, bolted to the principal rafters. The common rafters are to be wrought and chamfered, and the slate boarding will be wrought on account of being exposed to view. As the pitch of the roof is made to suit the character of the building, this mode of finishing will give great additional height to the interior, and add considerably to the effect, and at a less cost than the more customary horizontal ceiling. The church will afford sittings for 1,075 persons; nearly one-half will be free. The entire cost of the church will be under £3,400.

A New Roman Catholic Cathedral is proposed to be erected on a magnificent scale in York. The ground and buildings have already been purchased, and some of the latter have been pulled down. Upon the site chosen a monastery formerly stood. The ground, which extends from the Holy Trinity Church to the Bar, is to be laid out as a crescent, in the centre of which the cathedral is to be erected. Mr. Pugin has been selected as the architect, and the works are to be commenced immediately.

Incorporated Society for building Churches and Chapels.—At the last meeting of this indefatigable and most useful society, held at their chambers in St. Martin's Place, Trafalgar Square, London, the Lord Bishop of Durham in the chair, the principal business transacted was voting money for the following purposes, viz.:—Towards building a church at Westpool, Somerset; for building a chapel at Blackgate, Durham; building a church at Llanfynnidd, Flintshire; building a chapel at Kidderminster, Worcestershire; building a chapel at Dursley, Gloucestershire; building a chapel at Hardway, Hampshire; rebuilding the Church at Llanamore, Denbighshire; towards enlarging the church at Arlington, Devon; for enlarging by rebuilding the church at Basford, Warwickshire; towards repairing the church at Holme, Yorkshire; towards building a gallery in and repewing the church at South Lynn, Norfolk; repairing the church at Bradford Abbas, Dorset; building a chapel at Crook, Durham; enlarging the church at Burghfield, Berkshire; enlarging the chapel at Newton Heath, Manchester; being in all sixteen grants, amounting to several thousand pounds, all supplied by voluntary subscriptions to enlarge the means of spiritual instruction, chiefly by increasing free sittings.

Calcutta Cathedral.—The Bishop of Calcutta has forwarded to the Society for promoting Christian Knowledge a report, in which will be found much interesting matter relative to the cathedral in course of erection in that diocese. The bishop says, "It is hoped that in little more than two years from the present time, perhaps on the feast of the Epiphany, 1844, the cathedral may be ready for consecration. The style of architecture originally proposed has been adhered to, except where the climate and soil of Bengal have interfered. It is Gothic, modified by the circumstances just alluded to; that is, Indo-Gothic. The extreme length of the building, including the buttresses, will be 247 feet, and its width 81 feet, and at the transepts 114 feet. The height of the tower and spire from the ground will be 201 feet, and of the walls to the top of the battlements 59 feet. The internal dimensions of the main body of the cathedral will be 127 feet in length by 61 feet, the height 47 feet. The 127 feet will probably be subdivided into a choir, a chancel, and a holy table precinct. The body of the cathedral, if full pewed, will accommodate about 800 persons, and if galleries should be added hereafter, and chairs occasionally placed in the aisles, as is done in all Calcutta churches on the great festivals, 1300 or 1400. The transepts also, lantern, and western verandah, should they ever be wanted for congregations of catechumens or Sunday schools, would furnish above 400 additional seats. The capacity of the cathedral will not be less, therefore, than for 1700 persons. But the arrangement of the sittings will be ruled by circumstances and the convenience of the congregation, as all the stalls, pulpits, reading-desks, pews, and benches are intended to be moveable.

MISCELLANEA.

A NEW CEMENT, A SUBSTITUTE FOR GLUE AND CAULKING.

Amongst the numerous inventions submitted to the Lords Commissioners of the Admiralty, and referred by their Lordships to the committee of master shipwrights recently sitting at Woolwich dockyard, was a composition to be used in place of the substance with which vessels are at present caulked to render them water-tight. The experiments ordered to be made by the master shipwrights to ascertain its value when applied to the purpose for which it is intended, and the result, are interesting and satisfactory. Two pieces of African teak, a species of wood difficult to be joined together by glue, on account of its oily nature, had a coating of the composition applied to them in a boiling state, and in a short time afterwards bolts and screws were attached to each end, the joined wood placed in the testing-frame, and the power of Bramah's hydraulic engine applied to the extent of 19 tons, when the chain broke without the slightest strain being perceptible where the joining took place. A larger chain of one inch and a half in diameter was then applied, which broke with a strain of 21 tons, the joint in the wood remaining apparently as firm as at first. The utmost strain the cement can bear in this form, therefore, remains to be proved when experiments are made with larger chains. Four pieces of hard wood were then joined together, weighing in one piece 44 cwt., and carried to the top of the shears in the dockyard, a height of 76 feet, from which it was precipitated on the hard granite wharf wall below, without any of the joints yielding in the smallest degree. The results of these severe tests induced the Lords Com-

missioners of the Admiralty to communicate with Lieutenant-General Sir George Murray, G.C.B. and G.C.H., for the purpose of making experiments with it in the marshes at Woolwich, by bringing the full force of canon balls against it. Accordingly, a number of planks of oak 8 inches thick and 16 inches square were joined together with the cement, to together 8 feet in height and 8 feet in length of the side of a first-rate ship of war, without anything else in the shape of bolt or security to assist the composition; and it was set up as a target at the butt in the marshes. When a number of officers of the Royal Artillery were present to witness the experiment. Three shots were first fired, every one entering the target, the third in a direct line with the bull's-eye within three inches of its outer circle. The effects of these shots were wonderful, they tore the wood to pieces, and in only one instance, where the joint had not been good, they had no effect upon the cement.—A hole six inches and a quarter in diameter was then bored in the centre of the target, and an 32-pounder shell inserted and exploded by a match, which tore the wood to small splinters without in many places in the least separating the composition. This new invention is said to possess the power of expanding like India rubber in warm climates, and will not become brittle under the coldest temperature. It appears to be a great favourite with naval officers, as it is so clean, having only the appearance of French polish. The name of the inventor is Mr. Jeffrey.

The substances of which the cement is composed are simple, being merely *shell-lac* and *india-rubber dissolved in naphtha* in certain proportions; and being insoluble in water, the purposes to which it may be applied are numerous. Its value is about half the expense of common glue, the saving to the country by its universal adoption will be incalculable, as the inventor has been employed in experiments with it for upwards of two years, and has found that in the absence of great friction it is in a manner imperishable. An experiment was tried in the dockyard, which shows the value a supply of the cement will be to vessels which may be damaged at sea. Eight pieces of wood were joined together in the form of a mast, and a strain applied to them and to another mast of one piece of wood. The latter gave way first, and the other only broke after being considerably bent and the application of a rather great strain. By this substance, therefore, it is certain that ship carpenters can have no difficulty in effecting repairs at sea, which could not be done under any other circumstances.

Scott's Monument.—An engraving has just been published, from a drawing by the architect, Mr. Kemp, of the monument to the memory of Sir Walter Scott, at Edinburgh. It is a Gothic elevation, something in the style of what are called "crosses," and bears in some portions a resemblance to the great tower of the Cathedral at Antwerp. It is in style between the florid and the simple Gothic, having flying buttresses, finials, crockets, &c., and being ornamented with quatre feuilles, and more minute embellishments. There are many tabernacles, but they are not occupied by figures. The statue of Sir Walter is placed in the centre, beneath the principal arch; it is robed in a flowing drapery, and stands on a pedestal. The pedestal does not partake of the character of the building, and gives rather an incongruous effect to the whole. There is an appearance of lightness and elegance about the design, but it may be questioned whether the building has not too much of the monastic or clerical style to suit exactly the character of him it is intended to commemorate.

Patent Wire Rope.—These ropes are likely, on account of their economy, to become of extensive use for forming foot bridges over canals, and deep cuttings of railways. Two wire ropes made at Mr. Andrew Smith's works at Poplar, 100 ft. long, 2½ in. in circumference, and weighing 2½ cwt., cost 5*l.* 5*s.* formed the main chain for a suspension foot bridge on the South-western Railway, near the Weybridge station.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 28TH APRIL TO 26TH MAY, 1842.

Six Months allowed for Enrolment, unless otherwise expressed.

HENRY BARCLAY, of Bedford-row, for "a composition or compositions applicable as tools or instruments for cutting, grinding, or polishing glass, porcelain, stones, metals, and other hard substances."—Sealed April 30. (Four months.)

JOHN ROBINSON, of Watney-street, Commercial-road East, engineer, for "improvements in windlasses and capstans."—May 3.

JOHN RAILTON, of Blackburn, machine-maker, for "certain improvements in machinery or apparatus for weaving."—May 3.

GODFREY WETZLAR, of Myddleton-square, Clerkenwell, for "improvements in rendering fabrics water-proof." (Being a communication.)—May 7.

JOSEPH WARREN, of Heybridge, Essex, agricultural implement maker, for "certain improvements in ploughs."—May 9.

FRANCIS PRIME WALKER, junior, of Manchester, coal merchant, for "certain improvements in the manufacture of candles, candlesticks, or candle-holders, and in the apparatus connected therewith."—May 9.

GEORGE HAIRE, of Manchester, gentleman, for "certain improvements in machinery or apparatus for sweeping and cleaning chimneys and flues."—May 9.

THOMAS EDGE, of Great Peter-street, Westminster, gas apparatus manufacturer, for "certain improvements in apparatus for gas-water and other fluids."—May 9.

SAMUEL HALL, of Basford, C.E., for "improvements in the combustion of fuel and smoke."—May 9.

JACOB WILSON, of Wigmore-street, Cavendish-square, upholsterer, for "certain improvements in bedsteads."—May 9.

WILLIAM SANDERSON, of Aldermanbury, London, silk-manufacturer, for "improvements in weaving fabrics to be used for covering buttons."—May 9.

JOHN MELVILLE, of Upper Harley-street, Esq., for "certain improvements in propelling vessels."—May 11.

JOHN BROWNE, of Brighton, gentleman, for "improvements in the manufacture of mud-boots and overalls."—May 12.

THOMAS WILLIAMS, of Bangor, smith, for "an improved churn."—May 17.

WILLIAM BRUNTON, of Neath, Glamorgan, C.E., for "an improved method or means of dressing ores and separating metals or minerals from other substances." (For the colonies only.)—May 19. (Four months.)

JOSEPH GIBSON, of Birmingham, manufacturer, for "certain improvements in axletrees and axletree-boxes."—May 23.

JOHN BENNET LAWES, of Rotherhampstead, Hertford, gentleman, for "certain improvements in manures."—May 23.

JOHN BISHOP, of Poland-street, Westminster, jeweller, for "a new or improved construction of brake apparatus applicable to railway carriages."—May 23.

THOMAS MIDDLETON, of Loman-street, Southwark, engineer, for "an improved method of preparing vegetable gelatine or size for paper, and also an improved mode of applying the same in the manufacture of paper." (Being a communication.)—May 23.

WILLIAM TUDOR MABLEY, of Henrietta-street, Covent-garden, mechanical draftsman, for "improvements in machinery or apparatus for making nails." (Being a communication.)—May 23.

BENJAMIN COOK, junior, of Birmingham, brass-founder, for "improvements in the construction of bedsteads, both in metal and wood."—May 23.

FREDERICK GOOS, of Manchester, jacquard machine-maker, for "certain improvements in the jacquard machine or apparatus, to be used or employed in looms for weaving."—May 23.

SIR JAMES MURRAY, of Merrion-square, Dublin, Doctor of Medicine, for "an improved method of combining various materials in a manner not hitherto in use for the purpose of manure."—May 23.

JAMES PILBROW, of Tottenham, engineer, for "certain improvements in steam engines."—May 23.

WILLIAM GEEVES, of Old Cavendish-street, gentleman, for "improvements in machinery for cutting cork."—May 24.

JAMES STEWART, of Osnaburgh-street, Regent's-park, piano-forte maker, for "improvements in hinges for piano-fortes and other purposes."—May 24.

THOMAS WATERHOUSE, of Edgely, Chester, manufacturer, for "a certain improvement or improvements in machinery for carding cotton, wool, flax, silk, and similar fibrous materials."—May 24.

JOSEPH DUCZ, of Wolverhampton, lock-manufacturer, for "an improved lock and key to be used therewith, and an improved slide bolt for the said lock, applicable also to other purposes."—May 24.

JAMES BOYDELL, junior, of Hope Farm Works, Dudley, for "improvements in the manufacture of keel plates for vessels, iron gates, gates-posts, fences, and gratings."—May 24.

JAMES POTTER, of Manchester, manufacturer, for "certain improvements in machinery for spinning cotton, flax, and other fibrous substances."—May 25.

PETER KAGENBUSCH, of Whitby, York, for "an improvement in the dyeing of wool, woollen cloths, cotton, silks, and other fabrics and materials."—May 26.

TO CORRESPONDENTS.

"A Land Surveyor" will see that we have complied with his request; we will endeavour to give the magnetic variation periodically.

"O. T." We have received his valuable communication on iron, &c.; he shall hear from us by post.

"B. G." His communication was accidentally mislaid—we will answer it next month.

"A Subscriber" will find in the October Number of 1840, Vol. 3, p. 334, rules for computing the amount of earthwork in cuttings, embankments, &c., by Mr. Hughes.—Geological communications are admitted in the Journal.

"Juvenis" We have no knowledge of any locomotive engine having been constructed upon the plan proposed by him.

"A Subscriber of Derby." The conventional marks to indicate that the ditch and fence D. & B. belong to him, and on A to his neighbour. We do not understand the sign on the side C; we have never seen it used in the way shown. The area of the field will also be a guide or rather a check; the quantity belonging to him can be computed from the plan, as the boundary lines are drawn to the verge of the ditch.

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, III, and IV, may be had, bound in cloth, price £1 each Volume.

DIRECT ACTION ENGINES BY P. BORRIE & CO DESIGNED NOV^r 1841.

MARINE ENGINES,

By P. BORRIE & Co., ENGINEERS, TAY FOUNDRY, DUNDEE.

*Designed November, 1841.**(With an Engraving, Plate VIII.)*

THESE engines belong to that class generally denominated direct action engines: in this respect they are similar to other engines of that class. Their peculiarity consists in the novel arrangement of the air pump and condenser. The following particulars of their construction and peculiarity have been furnished us at our request, by Messrs. Borrie and Co.

The collective power of the two cylinders by formula,

$$\frac{\text{area of cylinder} \times 7 \times 210}{33,000} = 352 \text{ horse power,}$$

but by taking the pressure on the piston at 8.5 lb., and the velocity at 215 ft. per minute, the power will be 426 horse power. The strength of the engines and evaporating power of the boilers are adapted for the full power. The engines occupy a space of 10 ft. fore and aft the vessel, and 22½ ft. transversely. The engines, boilers, space for firing boilers, and coal boxes, capable of containing 400 tons of coals, calculated at 48 cubic feet per ton, in a vessel with engine room in the clear 34½ ft. broad, by 23 ft. deep, only require 55 ft. fore and aft. The ordinary length fore and aft allowed in the Government steamers for engines, &c. of the above power is 65 ft. With 65 ft. 560 tons of coals can be stowed in the coal boxes. With these engines, therefore, a space of 10 ft. fore and aft the vessel may be made available for other purposes, or an additional 160 tons of coals to the ordinary quantity apportioned to the coal boxes. The coal boxes are so arranged that they afford protection to the engines and boilers from shot, which are placed below the vessel's load water line.

The weight of one pair of engines	110 tons.
„ the paddle-wheels (common construction)	25 „
„ the boilers, with mounting	81 „
„ the water in boilers	55 „
„ the coal boxes	18 „
Total	289 tons.

The following explanation will show the construction of the condenser and air pump:—One condenser, *a*, fig. 6, and one air pump, *g*, serve for both engines. The air pump is double acting, and has four valves, *d' d' e' e'*. The valves *d' d'* correspond with the foot valve, and the valves *e' e'* with the discharge valve of an engine fitted with the common lifting air pump. This description of air pump has pistons similar to those used in steam cylinders, and packed with metallic packing in the same manner. Communicating with each end of the pump there are valves opening inwards, *d' d'*, and others outwards, *e' e'*, being four valves to each pump; by this arrangement the piston, *f f*, alternately draws and forces, at each half stroke of the engine. The passages are of one casting with the pump, next and jointed to the sides of the condenser, as at *r r r r*; doors, *c c*, on the sides of the condenser opposite these passages admit of ready access to the valves: the pump is placed at the bottom of the condenser. To render a stuffing box unnecessary on the pump cover, *o o*, for the pump rod, a tube, *n n*, extends from the pump cover, *o o*, to the cover on the top of the condenser, *s s*, in which the pump rod, *g*, works: a suitable stuffing box, *m m*, and gland, *l l*, for the pump rod are provided in the cover on the top of the condenser. The double action air pump possesses several advantages over those of the common construction; among these it may be noticed that one double action pump will do the work of two with only the friction of one single action pump, the dimensions of both being equal; so one of the former to do the same amount of work as one of the latter will only require to be of half the area, with the same length of stroke. The effective action of this pump being at every half stroke, a much steadier and purer vacuum will be maintained in the condenser than by the common pump, whose action

is only at the termination of every full stroke of the engine. Its liability to become deranged is not greater, and the difficulties in remedying these derangements when they have occurred are less than in the common pump. Connected with the latter are the foot, discharging, and bucket valves; for obtaining access to either of the first two of these valves, the jointing of a separate door has to be undone, and for the third several disconnections have to be made, and the air pump cover has to be lifted. In some arrangements of engines the whole of these valves are of very difficult access; to obtain access to the valves in the double action pump the undoing of two doors is only necessary. Although the valves at one end became deranged in action, yet the pump with the valves at the other end would work as a single action pump, and the engines continue in operation until opportunity was afforded for repair. The repair could be very speedily effected, by always having in readiness a set of valves to replace those that became defective. If the valves of the common pump get deranged, the working of the engine is completely suspended. In the arrangement of engines with this pump, it is shown in fig. 6 as wrought by a crank, forged of a piece with the intermediate crank shaft of the engines. The perpendicular position of the pump rod is maintained by a guide pulley, *i i*, working in guides, *j j*, bolted to the engine framing, *I I*.

It has been correctly maintained that an engine air pump with a solid piston or plunger, as hitherto constructed, will not produce so pure a vacuum as a lifting valve bucket of the common construction. This will hold true in respect to a single action plunger air pump which only expels the water and gases by its downward stroke; for as the gases are always in position above the surface of the water to be expelled, the descent of the plunger will lessen their volume and increase their density to an extent corresponding to what would result from being subjected to a pressure equal to that required for expelling the water. There being always a head of water in the hot water cistern pressing against the discharge valves, these gases can only be very partially expelled from the pump chamber. On the ascent of the plunger, and re-opening of the valve communicating with the condenser, they (the gases) will partially return to the condenser, (as a less head of water in a partial vacuum will offer less resistance to their ingress,) and partially impede the free flow of the water in it to the pump chamber. These defects impair the efficiency of the engines, from the consequent imperfect condensation, and impurity of vacuum; no such defects obtain in a double action force pump, as applied to an engine. In fig. 6 it will be noticed that the passages between the air pump and three of the lower sides of the condenser will always be filled with water, during the ascending stroke of the plunger piston to a level with the lower side of the piston plunger, and during the descending stroke to a level with the lower part of the upper foot valve seat. These passages, however, being specially made of very small cubical capacity, will not admit of more water remaining in the bottom of the condenser, on the cessation of the engines from work, than what remains in a condenser and bottom of air pump chamber of the common construction. The difference between the level of the lower side of the piston plunger and the lower part of the lower foot valve seat only admits of the water entering into the pump chamber during the ascent of the plunger, in the limited time afforded by a half revolution of the crank. This precludes an ingress, to any injurious extent, of gases to be acted on by the return of the plunger, in manner as resulting from the use of a single action plunger pump; but on the upper foot valve opening, during the descent of the plunger, opportunity is afforded for the admission of the gases into the upper part of the pump chamber. During the ascent of the plunger, these gases being in position above the surface of any water that may have entered with them, will be first expelled through the upper discharge valve, *e'*, into the hot well, *p*. The expulsion of the gases by a double action plunger pump is, therefore, as efficiently accomplished as by the common bucket valve pump; and the objections against the use of a single action force pump, when urged against it, are unfounded.

In the drawings and description one of these double action air

pumps is represented as sufficient for two engines, but under certain circumstances two would be preferable. The space and weight required for a pair of engines with two double action air pumps would not much exceed the space and weight with one, and still be very considerably under what two common bucket valve pumps would require.

REFERENCE TO THE ENGRAVING.

Figs. 1 and 2 side view; figs. 3 and 4 section; fig. 5 plan; and fig. 6 section of air pump and condenser. Similar letters refer to similar parts on all the figures: A, cylinders; B, pistons; C, piston rods; D, connecting rods; E, crank pins; F, cranks; G, crank and paddle wheel shafts; H, crank shaft entablatures; I, framings; K, piston cross-head guides; L, cylinder covers; M and N, force and bilge water pump wipers; O and P, steam valve, traversing shaft wipers; Q, piston valve spindles; R, piston valves; S, expansion valves; T, cross head guide pulleys; U, piston valve casings; V, expansion valve casings; W, steam pipe glandular joints; X, columns forming lower part of framing; Y, engine deck beams of vessel; Z, cylinder water scape valves.

Fig. 3: *a*, condenser; *b*, passages from condenser to foot valves; *c*, valve doors; *d' d*, upper and lower foot valves; *e' e*, upper and lower discharge valves; *f*, air pump piston plunger; *g*, air pump plunger rod; *h*, air pump connecting rod; *i*, air pump cross head pulley guides; *k*, crank for working air pump; *l*, air pump piston rod gland; *m*, air pump piston rod stuffing box; *n*, pipe for rendering unnecessary a stuffing box on air pump cover; *o*, air pump cover; *p*, hot well cistern; *q*, air pump chamber; *r*, jointings of air pump to sides of condenser; *s*, condenser cover; *t*, bilge water pumps; *u*, feed pumps; *v*, valves for closing eduction passages, in the event of one engine being wrought singly.

THE ROYAL MAIL STEAM PACKET COMPANY.

WE admire the adventure and majesty of this undertaking; we respect, both as merchants and men, those who preside over its destinies; but we look upon them as the most ineligible managers of a steam packet company that the annals of steam enterprise can exhibit, and are quite worn out with the untractable incapacity which shines through all their proceedings. Never was an enterprise begun under happier auspices. With a directory numbering some of the most august names among British merchants, with an influential connexion abroad, a most respectable proprietary at home and a most beneficial contract with the Government, success appeared certain and rivalry impossible; and never did mismanagement more effectually render "these rich gifts poor," or more speedily transform a scene of noble promise into a chaos of withered hopes, forlorn greatness, and wide-spread desolation.

We have patiently waited month after month, in the fond hope that some such amelioration would be accomplished as would at least give the enterprise a chance of success. We have suggested—we have remonstrated—we have entreated: and holding in mind the deep interest which many of our friends have in the undertaking—considering the baneful effect which the mismanagement of this company would indirectly exercise upon other companies, even the best managed—and foreseeing the deplorable consequences that would ensue to the national interests in general, and to the interests embarked in steam navigation in particular, from the utter failure of this scheme—we have left no stone unturned to induce the voluntary adoption of such measures as are best calculated to avert such a catastrophe. But it all will not do. The directors, deaf to the outcry of the public, which is roused to a man against them—regardless of having rendered themselves the subjects of unprecedented odium and universal derision—heedless of the pressure of accumulating difficulties, which every instant threaten to overwhelm them—*persevere*, nevertheless, in the very course that has already created all these disasters, and are still distinguished only for the same inordinate self-sufficiency, the same

futile dogmatism, and the same wanton temerity, which characterized the first hour of their hapless administration.

It becomes, then, a question of supreme importance, What remedy is to be sought for this state of things? and it concerns the proprietary deeply that a prompt and judicious answer should be given to this question. Happily the answer is not a difficult one; for as it would appear to be indisputable, and is indeed the universal sentiment, that mismanagement has occasioned all the past evils, the obvious way to prevent the recurrence of those evils is to change the management. This, we presume, the proprietary have it in their power to do; and if they have not, it would be a thousand times better to break up the Company altogether, than to endure the continuance of the present alarming state of things. It is the wisest policy to look the difficulties of the question fairly in the face, and certain it is that a bad compromise now is better than the prosecution of a scheme which, under the existing conditions, must terminate fatally. It is high time that the proprietary should search the business to the very bottom for themselves, and insist upon the execution of such measures as are essential to the general good. It is the only chance they have of saving any thing from the embers.

The very christening of this Company introduces us to—if not a species of artifice, at least to something so very like it that we are at a loss for any other name by which to distinguish it. We should be glad to know why this company is called "THE Royal Mail Company," as if there were no other Royal Mail Companies besides it. The City of Dublin Company, the Peninsular and Oriental Company, the Halifax Company, and others, are quite as much entitled to the appellation as this helpless leviathan; they, too, carry letter bags: and whether the design of this arrogated distinctive title was or was not to delude the ignorant into the belief that this Company possessed some peculiar immunity, or maintained some intimate species of connexion with Government not common to its contemporaries, such certainly has been the effect. But we pass over this trifling delinquency—though, in our eyes, unfair to other companies, and unworthy of a great enterprise, to notice topics of more stirring interest.

The assumed average speed of the vessels is at least one knot per hour too high.—The vessels have never kept their times, and they never can do so. The computations of the average speed are founded upon hypothetical and visionary considerations, not upon a knowledge of the performance of other vessels. The average speeds of the Great Western and the Tagus, as determined by the actual results of a number of voyages, are 8.3 and 8.25 knots respectively; and those vessels are among the most efficient afloat, certainly quite as speedy as any of the West India Mail Company's vessels. Yet the average speed which these last vessels are pre-determined to perform is, in some cases, as high as 10.4 knots per hour, and in no one instance so low as that of the ascertained speed of the Tagus or Great Western. Besides, the times of the mail arrivals should not be the times due to the average speeds but to the minimum speeds; the mails should never be late except from some extraordinary stress of weather, or some accident to the machinery. The times allowed for coaling are short enough under the most auspicious circumstances, and cannot be reckoned average times. The directors, in respect of time, have agreed to do more than they can do, or indeed than, with their vessels, can be done; and even were the contemplated speed attainable with the present vessels, it would be highly inexpedient to attain it, as such could only be done at an expense altogether disproportionate to the benefit derived. The consumption of fuel and general expense of maintenance increase with the speed in a wonderfully rapid ratio. The resistance increases as the square of the velocity, the power necessary to overcome that resistance as the cube of the velocity, and the expense in a more rapid ratio still, on account of the increased size and immersion of the ship. A vessel which, at the speed of 6 knots per hour, would only cost 1*l.* per hour for coals, would, at the speed of 12 knots per hour, cost 10*l.* per hour, so that the expense of propulsion through the same distance is 5 times greater with the greater speed. To look for an increased speed, then, as any palliation of the existing difficulties, would be preposterous; it would only make the

matter so much the worse, even if attainable, by adding fearfully to the expense.

The route is badly arranged.—There are too many exact dependencies and nice reciprocations involved in it, and it is also too circuitous. The whole arrangements, indeed, upon this head are so complicated as to be scarcely intelligible, and too visionary to be practicable; and the utmost confusion appears to have arisen in consequence. The movements of this vessel are dependent upon the movements of that vessel, and the movements of this last upon those of a third; so that the detention or occurrence of accident to one of the chain breaks the continuity, and throws all into confusion. In this respect a transmissive line of steamers is similarly circumstanced to a railway operating by stationary engines—an accident at any one of the stations stops the whole line. The several stations appear to have been injudiciously chosen; the grand rendezvous at Turk's Island, where the *Medina* was lost, appears, in particular, to be extremely ineligible. We tremble at the anticipations of a winter's storms among the intricacies and dangers incident to the navigation of these channels—studded as they are with rocks, banks, and islands. The Company, it is true, has had many disasters, but has not yet had a *minor*.

The vessels are all too large.—Their maintenance is consequently too expensive for the trade to bear. The mere expense of engine room wages per month is £200 for each vessel, and about as much more for sailors, &c.; nevertheless the vessels are inadequately manned. The wages and cost of victualling the crews of the several vessels cannot be much if at all less than £100,000 per annum. Taking the cost of each vessel at no more than £60,000, and as there are or are to be 14 vessels, $60,000 \times 14 = \text{£}840,000$, and adding £60,000 for the purchase of the *City of Glasgow* and *Acteon*, as well as the sailing vessels, the total capital of the Company embarked in vessels, without leaving them a penny in hand to carry on their business with, will be just one million sterling. The insurance upon this at 6 per cent. will be £60,000 per annum, and making the common allowance of 15 per cent. for a sinking fund and wear and tear, the amount of this item will be £150,000 per annum. The duration of a voyage—that is, the time under weigh from England to St. Thomas, Nassau, and round by Bermuda back again to England, is in round numbers computed by the Company at 1000 hours, and the consumption per hour in the greater number of the vessels is about 25 cwt.: $1000 \times 25 \div 20 = 1400$ tons of coals consumed per voyage $\times 24 = 33,600$ tons consumed per annum upon the main line. Adding one half of this for the consumption upon the branch lines and that of the *Acteon* and *City of Glasgow*, the total consumption per annum will be 50,400 tons, and much of this, taking into account the expense of freight, transshipment, &c., will cost very little less than 2*l.* per ton. Adding to the expense of coal that of engine-room stores, viz. oil, tallow, waste, white and red lead, rope yarn, furnace bars, and the numberless et cetera which every one acquainted with steam navigation as extended to foreign countries knows to be requisite for the performance of a voyage, the amount of these united items—that is, of coal and of these various engine stores—cannot be less than £100,000 per annum. The number of passengers, sometimes 5 or 6, rarely exceeds 20 or 30: taking 20 as the average number, and assuming that they all come the greatest distance, the passage money due to which is 62*l.* per head, and that the amount of the freight is always equal to that of the passage money, the receipts and disbursements will stand as under:—

ANNUAL RECEIPTS.

20 passengers at 62 <i>l.</i> , less victualling = 46 <i>l.</i>	£
$20 \times 2 \times 46 = 3280 \times 24 =$	78,720
Cargo, bullion, &c.	78,720
Intermediate passengers, &c.	10,000
Mail money	240,000
	£407,440

ANNUAL DISBURSEMENTS.

Wages and victualling crew	£100,000
Insurance at 6 per cent.	60,000
Coal depots	10,000
Wear and tear, and sinking fund	150,000
Coal and engine stores	100,000
	£420,000

Thus it would appear that, at the lowest calculation of expense, supposing that the speed is what the company anticipated, and that the enterprise is better conducted than it ever will be conducted by the present management, the excess of the expenditure over the receipts is £13,000 per annum, and this without the charge of a penny for management, clerks, offices, &c., or a fraction of dividend to the proprietary. So much for the expediency of using leviathan vessels.

We hear that the directors, not satisfied with the havoc they have already wrought, have it in contemplation to establish extensive workshops—to become, in fact, engineers, as the Great Western Company attempted to become. We question the legality of this measure, the funds of the company having been subscribed for a specific object; but, however that may be, we are quite assured of its inexpediency. In the first place, what can a circle of steam tyros know of the management of such concerns? Has their past management been such as to induce the desire, on the part of the proprietary, to embark in a further speculation? In the second place, the contemplated measure would be an act of injustice to engineers, many of whom are extensive proprietors, and who have no right to see their own money squandered in establishing an injurious though unavailing competition with themselves. We presume it was with an eye towards some such measure, that the directors took such pains to have all their engines of a different construction, so that a mould or a spare piece of machinery answerable for one should be altogether unsuitable for another. We must, in this instance, give the directors credit for greater foresight and a more skilful adaptation of means to an end than usually distinguish their procedures; for we must certainly admit that a more effectual method of rendering repairs difficult and expensive, of rendering an infinite assortment of spare machinery indispensable—in short, of rendering it necessary to keep a heavy engineering establishment perpetually occupied, could not have been devised by the most perverse ingenuity. Nevertheless, though much unnecessary expense and inconvenience are thus entailed upon the Company, we do not think it therefore necessary to attempt the mitigation of those evils by the creation of a still greater one; and the directors must pardon us for insinuating, that those persons who already possess the moulds of the various assortments of machinery—who already have workshops, tools, and, what is better than all, who have *skill*—may possibly be able to execute repairs upon more advantageous terms than those who have all of these to purchase. Instead of seeking to squander money in plaster and whitewash, the directors should think of paying some small dividend to the shareholders. Workshops and patterns, though they may cost a great deal, will sell for very little, and there is no proposition more self-evident to us, than that these very estimable *cognoscenti* would very soon *do* for a steam factory, as effectually as they have done for a steam packet company. But so far is it from the intention of the directors to declare a dividend, that we hear it rumoured they intend, in violation of their guarantee, to make a further call upon the shareholders. This call, we are very sure, will be resisted, but that it will be made we are as thoroughly assured; and the best thing the shareholders can do is to at once convene a meeting among themselves, to take the necessary steps for resuming their delegated authority. There are among their number men of cool and clear heads, who well know what steam navigation is, whose advice might do much to retrieve the present unhappy state of affairs, and the shareholders should at once decide upon taking the management into their own hands, until the requisite steps can be taken for appointing another executive. Let a meeting, then, of the shareholders be held; let a resolution be carried, to the effect “that

in consequence of the turn the affairs of the Company have taken, the public has lost all confidence in it; and that it appears to the proprietary that the only way of restoring confidence, as well as of promoting the general interests of the Company, is to request the directors to resign; and that with the view of preventing any obstruction to the effectual introduction of a better system, and of giving the public confidence in the reality of its introduction, as well as of advancing the interests of the Company, it is desired that the resignation of the directors should be accompanied by the resignation of all the subordinate officials." As men of character and station—which the directors are—they could not refuse to comply with such a requisition; and the Augean stable being fairly swept, let the affairs be put into the hands of the most circumspect, experienced, and energetic persons that can be pitched upon. There may be among the Company's officials one or two persons whom it might be expedient to retain; but no exception should be made on their account. A complete clearance is indispensable to success, and should it be thought expedient, after the new system has been established, to re-elect those persons, it can easily be done, and would then be unproductive of detriment. It is necessary to contemplate the substitution of smaller vessels for some of those at present plying; but this question and all others are comprehended in the fundamental one of efficient management.

In conclusion, we desire to repeat, that for the directors individually we entertain the most unmingled respect; we reverence them as English merchants and as English gentlemen, and we do not believe there is one among them whose high character and general commercial capacity are not universally appreciated and acknowledged. But in their collective character, as the executive of a great enterprise in steam navigation, they are only eminent for their egotistical perversity, and their utter destitution of every qualification indispensable to the exercise of so arduous a function; and we cannot but esteem it unfortunate for their fame, as well as injurious to their fortunes, that they ever assumed a direction of that technical and particular species which their other avocations must have rendered inconvenient, and for which their past pursuits have never rendered them fit. To manage steam enterprises properly requires much skill; that skill is only to be obtained by experience, and such experience the directors have never had. They may, perhaps, have relied for this upon their officials, but such reliance is not a proper one; for what is it but having directors with directors over them? Besides, not one of these same officials has ever had any experience in the conduct of commercial steam navigation upon the large scale, and they are, for the most part, far too theoretical and enthusiastic, to be safe guides or discreet advisers. It is true, time and experience might cure these failings, and in time, too, the directors might acquire sufficient knowledge and discretion to enable them to govern as they ought. But the Company would be ruined in the interim, and by the time these gentlemen had become proficient, there would cease to be a field for the display of their attainments. The particular management ought to be confided to two or three managing directors, who should be paid well for their services, and who should do nothing else. The board of directors should confine itself to the regulation of matters of finance—to the determination of measures of general policy—and to seeing that the managing directors did their duty. That there will probably be some difficulty in getting persons competent to fill the office of managing directors is undeniable, for talent such as that office requires is not likely to be unengaged; yet that eligible persons may be obtained we are perfectly convinced, and no sacrifice should be thought too great to obtain such auxiliaries, the very existence of the company being contingent upon its skilful management.

Let the proprietary then weigh well, proceed resolutely and act promptly. To attempt to disguise their present position would be idle—to shut their eyes to it, insane. We do not think their affairs irretrievable—nay, further, we are of opinion, that under proper management, this enterprise might become as flourishing and lucrative as it is now disastrous and alarming. But this consummation is neither accomplishable by the same measures nor the same men; and the

sooner new men and measures are chosen, the less dangerous will be the wound and the less difficult the cure. The proprietary have two courses before them; if they adopt the one they will continue unperplexed and become prosperous—if they persevere in the other they will very soon find themselves embarrassed, impoverished, and undone.

CANDIDUS'S NOTE-BOOK. FASCICULUS XXXVIII.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. If Michael Angelo was, as some have called him, a giant in architecture, he was also a barbarian in it. Many of his buildings are little better than stupendous puerilities; and all of them abound, more or less, with vices that would hardly be tolerated in any one else. Well may Vasari call his St. Peter's "*una fabrica terribilissima*," it being literally terrible enough in many respects. Memmo has pointed out in his "*Elementi d'Architettura*," many egregious solecisms in the works both of Michael Angelo and Palladio, and he might have extended the list of them to a much greater length. In regard to the latter, it is, indeed, astonishing that people—or at least some people—should continue to repeat the praises bestowed upon him a hundred years ago, for hardly can it be averred that he now stands in the same relative position he then did. It is also extraordinary that, while Palladio's name has become a metonym for excellence in art, that of Alessi should be comparatively obscure and seldom mentioned at all, notwithstanding that in comparison with him, the other is, at the best, tame and insipid. It is to Alessi that Genoa is mainly indebted for its title of *La Superba*, and for the stately and picturesque character of its palazzo façades. He has been as much undervalued as his Vicentine contemporary has been overrated. Even his name is not to be found in every biographical dictionary; nor, *horresco referens*, does Woods mention him at all in his "*Letters of an Architect*," although he says that Genoa may justly be proud of its palaces, which, by the bye, is all that he says about them!

II. A German periodical on the Fine Arts speaks of a house now nearly completed at Paris, for the banker Hope, which is somewhat larger than the Louvre, and when finished and furnished will cost about thirteen million francs! or upwards of half a million sterling! Is this a "*Munchausen*"? if not, how happens it that no rumour relative to such an architectural undertaking has found its way into any English journal? Had it been a new bonnet instead of a new Louvre, the pattern of it would have been in London in the course of four-and-twenty hours. This, however, is not the only instance of our extreme tardiness in obtaining information relative to what is going on in architecture upon the continent; and about which just as much is known as about the current literature of the continent. For the last twenty years our Anglo-German critics have been pestering us with Schiller and Goethe, Goethe and Schiller, and have gone on Schillering and Goetheing, and Goetheing and Schillering, as if all the rest of the literature were a mere blank. It is pretty much after the same fashion that those who speak of buildings at all, repeat the same cuckoo strain, to the tune of Parthenon and Pantheon, Pantheon and Parthenon, Vitruvius and Palladio, Palladio and Vitruvius, till we sicken of the very mention of them. Who is Cagnola? asks one; and, who is Canonica? who is Gärtner? who is Langhans? who is Rossi? who is Thon? who is Ottmer? are all questions in turn. Truly, there is as yet no railroad for architectural intelligence: it travels as slowly and as crawlingly as an old Yorkshire stage wagon. Perhaps at the end of the century, something will be known here of what has been going on in architecture upon the continent, during the two last decenniums.

III. "It not unfrequently happens that those who derive their knowledge from books are far better acquainted with things or objects than

those who have actually beheld them; because he who reads with attention will carefully ponder upon, and reconsider the matter under notice, whereas he who merely looks at things can afterwards give no clear account of them; so far, therefore, reading is more instructive than seeing." Such is the remark of Cervantes in his *Perales* and *Sigismunda*, a work that may be said to be very celebrated, although very little is known; and it is one corroborated by my own experience to a far greater degree than I could wish, for I have again and again found it impossible to obtain any sort of information relative to buildings, from those who have actually seen them. When questioned as to particulars, they tell you they did not notice this, they did not think of looking for that; this they quite overlooked, that they quite forgot to observe; so that what with their overlooking and their forgetting, you find there is no getting any thing out of them. According to their own confession they can describe nothing, nor can they remember any thing; nevertheless, instead of taking any shame to themselves for their ignorance, such people will give themselves airs of superiority merely because they happen to have seen what you have not, and have had opportunities by which they have not in the slightest degree profited. I once amused myself at the expense of a traveller of that description, who was giving me a long account of a building he had visited. Having suffered him to go on without interruption, and letting him have it all his own way, I placed before him a volume of engravings of the building in question, remarking they must be exceedingly incorrect and untrustworthy, since they did not at all tally with his description; in fact they did not agree with it—or rather his description did not agree with them, in any one particular. The consequence was, my gentleman looked very disagreeably astonished at finding himself so completely contradicted by evidence which he could not dispute.

IV. Though I never heard of him before, I am in no danger of now forgetting the name of the nonentity recorded by Nagler as "Philippus, an architect known to us by an inscription in Gruter's work, which says 'Philippus architectus maximus hic situs est.'" Truly there is not much here either to forget or to remember—nothing, certainly, worth knowing; although it is an exceedingly great curiosity in its way, as an article in a biographical dictionary of artists. It is rather too much à la John Britton, who has foisted into his dictionary the names of several such illustrious nobodies as carpenters, stone-masons, and other mechanical geniuses. Surely there is little occasion for peopling dictionaries of artistical biography with such mere ghosts and shadows and sounds, as are Philippus and not a few others who flit before us in Nagler's work, which is already so voluminous in itself, that, like *Falstaff*, it requires no further stuffing out. In fact Nagler seems to have pounced upon every name he could anywhere meet with, and has accordingly caught and preserved some excessively small fry, people whose names never appeared in print before, except in an exhibition catalogue, or a newspaper paragraph. This is being over-minute and scrupulous, more especially when we find that, notwithstanding such minikin exactness, he has omitted some names of the first magnitude. Will it be believed?—no, it is perfectly incredible—that, while he has given a place in his dictionary to many living architects, and other artists who are either comparatively or positively quite obscure, he has actually omitted that of CHARLES BARRY! This almost beats the anecdote told by Krilov in one of his fables, of the man who, telling a friend all the wonders he had just been examining in a museum of natural history—the shells, moths, and insects there exhibited, was asked by him what he thought of the elephant. "The elephant!—why bless my soul! I did not see the elephant at all!" After all, a parallel instance to that in Nagler may be found in Wolff's account of our English novelists, who, while he notices such bolstered-up mediocrities as Lady Blessington and other namby-pamby scribblers, does not bestow even a single word on Theodore Hook! Utterly incredible, yet positive fact.

V. There is an immense deal of cant in the world besides religious cant, and certainly no little of it infects both literature and art. I have just at my elbow a book where Shakspeare is eulogized in expressions that may be termed blasphemous, the writer observing, as if reproach-

ingly against the poet's contemporaries, that, notwithstanding his unrivalled excellence, he did not obtain from them "a tithe of the loving and reverent admiration we pay to the Creator of a world". This is rather too powerful for ordinary nerves, for when a man writes in such a strain of any other human being, instead of honouring the object of his adoration, he only disgraces himself, and compels us out of mere charity to suppose that he must be quite insane. Much as honest and sincere enthusiasm is to be commended in the literary man and the artist, it has its limits, and if it oversteps them, it becomes either raving madness or drivelling silliness. To hear some people talk, one would really imagine that the *Cartoons* of Raphael and the *Elgin Marbles* were the palladium of England—possessions far exceeding in value all its colonies, and its "either Ind." They speak of them as of things holy—as if their loss would be a loss to the entire world, and as if civilization itself would be extinguished whenever they cease to exist. In like manner the enthusiastic admirers of Grecian architecture are apt to speak of it as if the world would never have known what architecture was, or have had anything worthy of being so called, but for the pagan temples of Greece. Grecian architecture is, I own, truly admirable, *as far as it goes*, but then it goes a very little way indeed. Its resources are so exceedingly few—its alphabet so exceedingly scanty—the combinations it admits of are so very, very limited, that we may well be allowed to abate the demands made upon our admiration in its behalf, as being rather too extravagant. Well has it been observed by Goethe, that Grecian architecture may be compared to a clever and intelligent child, very superior, if considered only as a child—as such, perhaps a prodigy—nevertheless not at all equal in capacity to a grown-up person of ordinary mental ability. What Grecian architecture would have ultimately become, had it continued to thrive for ages without check or hindrance of any kind, can now only be conjectured; yet the probability is that it would hardly have advanced at all beyond the point it actually attained. Notwithstanding the poetical nimbus with which classical antiquity has been adorned, the whole constitution of ancient society and civilization was essentially barbarous, because essentially immoral: and could it be otherwise, seeing that their very religion tended to confound all sense of right and wrong, and their deities were little better than so many personifications of vice and baseness—profligate, cowardly, lying knaves and rogues, cuckold-makers, and pimps. A knowledge of the Greek dramatists may serve to recommend a man to an English bishopric, because such has been the case before now; but the reverence paid to classical literature as an element of education has, it may be feared, chiefly tended to keep up a moral taint, so that in consequence of such influence in its higher spheres, "society itself continues selfish, sensual, and belligerent." My pen is just such another unmanageable beast as John Gilpin's steed, for it has run away with me, till I have almost lost myself, and the reader lost his patience altogether.

ON THE SEPULCHRAL MONUMENTS OF SARDIS AND MYCENÆ.

BY WILLIAM RATHBONE GREG, ESQ.

(From the *Memoirs of the Literary and Philosophical Society of Manchester.*)

* * It is not uninteresting to observe how generally the monuments, erected in honour of the dead, have outlived those reared for the use or the luxuries of the living. Thus, in the East, we constantly meet with extensive cemeteries, standing alone in a deserted region, where the cities which peopled them have been entirely swept away, and where no human habitation can be found for many leagues. On the plain of Troy, the Tumuli are the only remaining monuments of a time celebrated beyond all others in the history of mankind;—the pyramids of Egypt have long survived the cities of the monarch who erected them;—at Mycenæ, the tombs of the Atridæ may be seen in their original integrity, though their palaces have left no vestige

behind them, and their massive citadel is fast crumbling into ruins;—and of the renowned and magnificent Sardis, the only uninjured relic which has reached our times, is the sepulchre of the sovereign who first raised it into splendour.

To whatever part of the world we turn our attention, we find barrows or tumuli in great abundance, and differing from each other but little, either in construction or in form. They are generally conical hillocks, of larger or smaller dimensions, constructed sometimes of earth, sometimes of stone, in some cases solid, in others containing a vaulted chamber. In our own country they are found in Cornwall, and more especially in Scotland and the Orkneys, where they are known under the name of *cairns*; Dr. Clarke relates having met with them abundantly in the Steppes, or vast plains in the south of Russia;—and I found considerable numbers in Roumelia, both north and south of the Balkan, and also in Servia and Bulgaria. Jefferson (in his "Notes on the State of Virginia,") describes many of them in different parts of the New World; in Africa they are said to be not unfrequent; and in Greece and Asia Minor they are seen in unusual quantities, and of extraordinary dimensions. Having had the good fortune to visit several of the more celebrated of these barrows, it may not perhaps be wholly uninteresting to the Society to hear a short description of the two which most deserve our attention, viz. those at Sardis and Mycenæ.

To commence with the latter. The plain of Argos, in the N.E. of the Morea, is an extensive semicircle of flat, and for the most part, marshy land, situated at the head of the Gulph of Nauplia, and apparently reclaimed from the sea at no very remote period, as indeed mythological history plainly indicates. It is inclosed by a vast amphitheatre of hills, among which is situated Mycenæ, the city of Atreus and Agamemnon, said to have been founded by Perseus, about 1300 B.C. Its remains are very accurately described by Pausanias, who flourished A.D. 180; though Strabo declares that in his time (B.C. 10) no vestige of it existed, and that its site was entirely unknown. It is not, however, easily to be found, even by those acquainted with its general position; for though myself and my companions were furnished with the best maps, and travelled Pausanias in hand, it was not till the second day's search that we were at length rewarded by stumbling upon the Citadel, among the low hills near the village of *Charvali*.

The Acropolis of Mycenæ is a rocky hill entirely surrounded by walls, which in many parts are still tolerably perfect, and, except at intervals, are of the oldest style of Cyclopian architecture. Of the Pelasgians or Cyclopes, to whom all the most solid and stupendous structures of ancient Greece and Italy are, by common fame, attributed, we know almost nothing; nor has the profound and patient genius of Niebuhr succeeded in throwing any material light on the origin, history, or achievements of this singular and powerful people. Their national existence would seem to have been almost terminated before the commencement of the historic era; and many of the most ancient and remarkable cities in Greece Proper and Magna Grecia appear to have been founded by them, either while existing as an independent people, or after their subjugation by other Greek tribes.
